EXTENT OF OPIUM SMUGGLING IN THE UNITED STATES. — During the past few months we have noted from time to time seizures of smuggled opium by federal officers in various parts of the country. Report from Washington, D. C., states that since the beginning of the present campaign against the illegal opium traffic over fifty raids have been made and that there has been seized a total of four tons of smuggled opium having a commercial value of $100,000.

NEWS OF THE ORIENTAL EPIDEMIC OF PLAGUE. — Reports during the past week seem to indicate an abatement of the bubonic plague epidemic in China and Manchuria. It is said that sanitary measures are being more strictly and generally enforced. European passengers on the Trans-Siberian railway, however, are now permitted to enter Pekin without quarantine.

Report from Berlin states that the German government has ordered medical inspection of all ships and crews arriving in that country from Chinese ports. The United States government has also established special precautions to prevent the entrance of the infection into the Philippine Islands, where there has been no case of bubonic plague for over three years.

### BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Feb. 21, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 40, scarlatina 36, typhoid fever 3, measles 101, smallpox 0, tuberculosis 69.

The death-rate of the reported deaths for the week ending Feb. 21, 1911, was 20.13.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Feb. 25, 1911, was 280, against 279 the corresponding week of last year, showing an increase of 1 death, and making the death-rate for the week, 21.19. Of this number 151 were males and 129 were females; 275 were white and 5 colored; 150 were born in the United States, 119 in foreign countries and 11 unknown; 51 were of American parentage, 196 of foreign parentage and 33 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 42 cases and 5 deaths; scarlatina, 33 cases and 3 deaths; typhoid fever, 3 cases and 1 death; measles, 70 cases and 0 deaths; tuberculosis, 57 cases and 18 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 51, whooping cough 4, heart disease 34, bronchitis 4. There were 30 deaths from violent causes. The number of children who died under one year was 41; the number under five years, 51. The number of persons who died over sixty years of age was 81. The deaths in public institutions were 118.

Measles at Portsmouth. — It is reported from Portsmouth, N. H., that there are at present over 300 cases of measles among children in that city, and that the public schools have been closed for a week in an effort to check the epidemic.

Conviction for Illegal Sale of Cocaine. — In the Boston Municipal Court last week an itinerant peddler, of Cambridge, Mass., was sentenced to three months' imprisonment for illegally selling cocaine. From this sentence he appealed.

A New Nurses Home in Woburn. — The new nurses' home of the Choate Memorial Hospital, Woburn, Mass., was opened last week for public inspection. The building, formerly a private residence, which has been completely remodeled and refurnished, contains a reception and lecture room, and will afford accommodation for the entire nursing staff of the hospital.

Industrial School Fair. — On Thursday and Friday of this week, March 2 and 3, is to be held at Hotel Somerset, Boston, the annual fair for the benefit of the Industrial School for Crippled and Deformed Children. The proceeds will be used to help towards defraying the running expenses of the institution.

Hospital Concerts for March. — It is announced that during the month of March, the concerts of the Boston Hospital Music Fund will be given as follows: On March 5, at the Helping Hand Home for Jewish Children, Roxbury; on March 12, at the United States Marine Hospital, Chelsea; on March 19, at the Kindergarten for the Blind, Jamaica Plain; on March 26, at the Home for Aged Colored Women, Boston.

Bequests to Hospitals. — The will of the late Sullivan Niles, of Cambridge, Mass., filed last week at East Combridge for probate, contains a bequest of $3,000 to the Cambridge Hospital.

The will of the late George W. Fifield, of Lowell, Mass., who died on Jan. 30, 1911, was allowed last week in the Middlesex Probate Court. It contains bequests of $20,000 each to St. John's Hospital, Lowell, and to the Lowell General Hospital.

Plans of the Forsyth Dental Infirmary. — The trustees of the Forsyth Dental Infirmary made public last week their tentative plans for the erection of the infirmary building. This will be located on a tract of land between Hemenway Street and the Fenway, part of which will be converted into a permanent park and playground. The building is to consist of three stories and two mezzanine floors, and will be equipped with the most approved facilities for all branches of dental work. The possibilities of service by such an institution to the community are very great, and it should do a work of great importance hitherto inevitably much neglected. Not only will it bring relief and prevent suffering for individuals, but it should become a center of research and a means not only of training in dentistry for many future practi-

tioners, but of education in dental and oral hygiene for coming generations.

MEDICAL INSPECTION OF SCHOOL CHILDREN IN BOSTON. — At a meeting last week of the Boston 1915 Health Conference, at the rooms of the Twentieth Century Club, Dr. Silas H. Ayer, who has recently resigned as chief school physician of Boston, called attention to the present unsatisfactory condition of medical inspection of school children in this city. His comments were in the line of similar criticisms made by Dr. David D. Scannell, formerly of the Boston School Committee, that the work of such inspection should be inadequate seems inevitable so long as the salary paid by the city to medical inspectors is too small to secure the devotion of a sufficient amount of time and energy by the physicians appointed. Dr. Ayer advocates the appointment of a single responsible chief for this work, with a suitable number of assistants adequately paid. Other addresses were made at the meeting by Dr. William B. Coues, Dr. Horace E. Marion, Dr. Cleaveland Floyd and by Dr. Durgin, chairman of the Boston Board of Health.

THE INSTRUCTIVE DISTRICT NURSING ASSOCIATION. — The twenty-fifth annual meeting of the Instructive District Nursing Association was held in Boston on Feb. 23. The annual report of the association, presented by the secretary, showed that during the past year 30 nurses have graduated from this practical training-school. The association employed during the year 47 nurses, who made 112,912 visits on 10,313 patients. Of these, 4,054 were visits for observation and instruction of 1,834 pregnant women. Miss Martha H. Stark, the superintendent of staff nurses, described the details of this and other aspects of the work. Other addresses were made by Miss Alice Higgins, general secretary of the Associated Charities of Boston, and by Dr. Howard T. Swain, of the Boston Lying-In Hospital, who particularly emphasized the value of the work done by the nurses in connection with the out-patient department of the hospital. The following officers of the association were elected for the ensuing year: President, Mrs. Katherine B. Codman. Vice-Presidents, Mrs. Helen Mumford and Miss Emily G. Denny. Secretary, Miss Gertrude W. Peabody.

## NEW YORK.

A LUTHERAN HOSPITAL. — A society has just been formed for the purpose of erecting and maintaining in the upper part of the Borough of Manhattan a fully equipped Lutheran hospital. For the past three years a medical service has been carried on by the Lutherans, and last year 1,200 calls were made and 364 patients treated.

CONGRESS SPRING PARK, SARATOGA, A STATE RESERVATION. — The famous Congress Spring Park, Saratoga, which has been in existence under private ownership for over a hundred years, has now been purchased by the village of Saratoga Springs for $100,000, and will be added to the New York state reservation. Some time ago a bond issue of $250,000 was voted by the taxpayers of the village, the proceeds to be devoted to co-operation with the state in the establishment of the reservation.

APPOINTMENTS — BEQUESTS. — Dr. Theodore Caldwell Janeway, son of the late Dr. Edward G. Janeway, who is Bard professor of the practice of medicine at Columbia University, and is now attending physician to St. Luke's and the City Hospitals, has just been appointed attending physician to the Presbyterian Hospital, in the place of Dr. W. Gilman Thompson, resigned. This appointment, it is stated, was made at the desire of the trustees of Columbia University in accordance with the recent tentative agreement between these and the hospital. Another new appointment at the Presbyterian is that of Dr. William G. MacCallum, professor of pathology at Columbia University, to the position of pathologist, in the place of Dr. E. L. Opie. This hospital has just been left, from the estate of the late Melville DeWolf, a bequest of $5,000 for the endowment of a free bed for children. Mr. DeWolf, who died on Feb. 9, also bequeathed $5,000 to Roosevelt Hospital for a free bed.

DEATH-RATE. — Dr. Guilfoy, registrar of records in the City Health Department, has made a report in which he states that if the average death-rate in New York during the decade 1900 to 1909, inclusive, had been maintained during 1910, no less than 13,066 more persons than was the case would have died, a favorable result which he attributes largely to increased sanitary control over disease. There were 2,203 fewer deaths than the ten-year average from pneumonia, 1,840 from tuberculosis, and 1,317 from Bright's disease and acute nephritis. His analysis of the figures shows that 6,000 lives of children under five years were saved, and 6,500 of persons between five and sixty-five years old, but less than five hundred above sixty-five. Among the diseases in which there were increases, instead of

decreases, in the number of deaths were cancer, organic disease of the heart, and cirrhosis of the liver. Appendicitis also showed an increase in mortality, probably because more cases, formerly classified under acute indigestion, were attributed to this cause.

## Current Literature.

MEDICAL RECORD.

FEB. 4, 1911.

2. *WELLS, J. G., AND LEVY, L. H. *The Use of Electricity in Chronic Disorders of the Stomach.*
3. GRAY, F. D. *Direct Transfusion.*
4. LERCH, O. *On Percussion and on Percussion of the Kidneys.*
5. WEIDLER, W. B. *Keratitis ex Acne Rosacea.*
6. DANNREUTHER, W. T. *The Recognition and Treatment of Gonorrheal Urethritis and Cystitis in Women.*
7. FAUGHT, F. A. *The Clinical Value of Blood-Pressure Studies.*

2. Wells and Levy report benefit from the use of electricity in six stomach cases — two of gastralgia, one of nervous regurgitation, two of chronic gastritis and one of gastric ulcer with atony. The negative electrode was placed in the stomach by means of a stomach tube and the positive electrode was applied to the abdomen. The writers consider electricity indicated in any of the chronic gastric disorders. For disturbances of secretion and in functional conditions with pain, galvanism is best, while in disturbed motor conditions faradism gives better results. [L. D. C.]

8. HANCOCK, C. R. *Appendectomy with Cocaine Analgesia: Report of Seven Cases.*

7. Freund reports a case of asphyxia neonatorum successfully treated by placental atration. Immediately after the birth of the child the placenta was manually loosened and delivered. The baby was placed in a basin of warm water, the placenta being held maternal surface upward, exposed to the air. Respiration was maintained in this way for thirty-five minutes. Whenever the child became cyanosed the turning of a stream of oxygen on to the maternal surface of the placenta brought about immediate recovery of color, and the pulse improved in quality. After thirty-five minutes the child began to cry normally and the cord was cut. [L. D. C.]

3. Robinowitch, using rhythmic excitation of about thirty volts of electricity, has been able to resuscitate dogs apparently dead from electrocution, over-etherization and over-chloroformisation, after the elapse of from one to five minutes and also demonstrated the value of this method in resuscitating a deeply cyanosed patient dying of morphine poisoning.

8. Nichols finds experimentally that sodium cacodylate has no spirillicidal action in rabbits infected with spirochete pallida when tested by Ehrlich and Hata's technic. Treatment with this drug does not interfere with a subsequent treatment with salvarsan.

9. Osgood and Lucas, experimenting with poliomyelitis virus on monkeys, have demonstrated that it was possible to transmit from monkey to monkey a typical poliomyelitis from the filtrate of the nasopharyngeal mucosa of two monkeys dying without other discoverable infections respectively six weeks and five and one-half months after the acute stage of the disease. In one case they were able to transmit the disease from the nasopharyngeal mucosa of a monkey dying in the acute stage. It was not found possible to transmit the disease from monkey to monkey by inter-cerebral inoculation of the cord and brain of those recovered subjects or from filtrates of the nasopharyngeal mucosa of a monkey in apparent good health, which had received a previous inter-cerebral inoculation of an active virus with only questionable prodromal symptoms but which had lived in closest contact with monkeys in the acute stage of the disease. These observations indicate that the virus of poliomyelitis can persist in a viable and infectious state in the nasopharyngeal mucosa in monkeys for several months after the acute period of paralysis has passed, and for a greater period of time than it survives in the central nervous system. The authors noted no case of transmission from monkey to monkey except by direct inoculation, although closest association with subjects in the acute stage has been maintained both by contact and the use of the same feeding utensils and materials.

10. Gilbride estimates that the secretion of pepsin in diabetes mellitus is frequently reduced and sometimes absent. Also gastric motility is usually increased and gastric secretion is frequently diminished.

11. Coburn quotes various experimenters who have found that so short an anesthesia with ether as fifteen

minutes causes a definite and demonstrable anemia. This does not improve often till after the fifth day and must retard convalescence even in favorable cases, and in critical cases may be the determining factor in producing a fatal termination. Chloroform produces even more destructive changes on the blood, while its degenerative action on the liver is well known. Ether increases the toxemia arising from infection. Recent investigation shows that this is due to the fact that ether impedes the functional activity of the leucocytes; in other words, lessens the patient's resisting power against the infection. Nitrous-oxide and oxygen, on the other hand, produce no such deleterious effect. Coburn makes a strong plea for the more general use of this latter anesthetic agent. [E. H. R.]

1. The deodorising power of a disinfectant is often taken as an index of its germicidal efficiency. This gives rise to a sense of false security. The authors describe the various methods of bacteriological standardization of disinfectants, the best of which are fundamentally the same. This method consists of a comparison with the efficiency of carbolic acid, from point of view both of time and dilution. The authors have introduced various modifications of what they consider the best method. It is essential to have

(1) Cultures exposed to a uniform temperature.

(2) Cultures measured carefully and with uniformity.

(3) Subcultures prepared from measured amount of exposed fluid.

(4) Subcultures prepared on most suitable media.

The coefficient is the mean between the strength and the time coefficients; i. e., the figure representing the degree of dilution of the weakest strength of the disinfectant that kills within two and one-half minutes is divided by the figure representing the degree of dilution of the weakest strength of the phenol control that kills within the same time. The same is done for the weakest strength that kills in fifteen minutes. The mean of the two is the coefficient.

From this can be determined the cost per unit of efficiency, the knowledge of which would be of great aid in practice. [L. H. S.]

1. Before operating upon an aneurysm of any large vessel, the efficiency of the collateral circulation should be known. With the knowledge of a good collateral circulation, an obliterative procedure, if unavoidably necessary, may be safely undertaken. The determination is obviously less difficult in the extremities than in the trunk or neck. For the extremities Matas describes tests which he has discarded. He then presents a modification of Moszkowicz's hyperemia test which he has found both simple and reliable. The test requires an apparatus to compress the artery above the aneurysm. For this purpose Matas has been using the Massachusetts Hospital compressor (description and picture given). In a case of aneurysm of the brachial artery, the compressor is applied to the artery above the aneurysm and tightened until the aneurysm is "stilled" and no pulsation can be detected in the radial and ulnar arteries at the wrist. The color and temperature of the arm below the compressor are observed. The compressor is removed, the arm elevated to drain all excess of venous blood, an elastic (Esmarch) bandage applied from the finger tips to the upper pole of the aneurysm, the compressor reapplied and the aneurysm kept stilled for five to eight minutes (inversely proportional to the age of the patient) and the bandage quickly removed with the compressor *in situ*. In case the collateral circulation is efficient, a hyperemic wave spreads from the compressor throughout the arm to the tips of the fingers, the blush persists a while, then fades. The rate of the wave and the duration of the blush are variable. In case the collateral circulation is not efficient, the wave will stop at some point between the compressor and the finger tips. The parts below this level will then be of waxy and cadaveric pallor. An appreciable wave or blush may not occur. A pink color, which can be made paler by pressure, however, indicates some circulation. Only an absolute waxy pallor indicates ischemia and ultimate death. If such pallor persists at the end of an hour, despite hot-air baths and massage, it is justifiable to conclude that the collateral circulation does not warrant obliteration of the parent artery. The possibility of embolism upon release of the compression is considered and measures to lessen the coagulability of the blood suggested. The second part of the paper is devoted to the determination of the efficiency of the collateral circulation of large arteries of the trunk and neck, especially the carotids. One hundred and sixty-eight experiments have been performed on the femoral and carotid arteries of dogs. The method may be called the immediate and total prophylactic occlusion of arteries. Aluminum bands (description and pictures given) have been found best. All vessels so clamped stood compression seventy-two hours without apparent microscopic changes in the intima.

6. After describing the preparation of Moorhof's bone wax, summarising the results from its use obtained by its originator, Meurer, and Silbermark, and after describing the technic of its use, Simmons gives abstracts of five cases of bone abscess in which he employed the wax. All the cases were operated upon over one and one-half years ago and the end results are given. The wounds of the only cases closed without drainage (3) healed by primary union with the subsequent formation of sinus. The cavities in all cases were evidently rendered sterile by the cleaning process and the dressings were easy and painless. The results of four cases may be called perfect. X-rays of two show the cavities filled with normal bone.

7. Thomas believes many cases of traumatic combined paralysis of the arm are due to laceration of the axillary portion of the capsule of the shoulder-joint and not to lesions of the brachial plexus or to inflammation of the

subacromial bursa. His argument is based upon personal cases and citations from the literature, clinical and post-mortem. Forced abduction of the arm may tear the axillary portion of the capsule of the shoulder-joint. Dislocation of the arm may result and persist. The arm in some instances may immediately drop to the side, from spontaneous reduction, or from simple sprain (tear of the capsule without dislocation). Extravasated blood, lymph and synovial fluid from torn vessels and joint capsule fall by gravity into the loose tissue of the axilla and are sufficiently irritating to produce perineuritis and neuritis of some of the axillary nerves. Coincident with this there occurs contracture of the capsule at the site of the rent due to its healing. There results scapulo-humeral limitation of motion and atrophy of those muscles of the shoulder and arm whose innervation has been impaired. The circumflex nerve, owing to its close relation to the joint capsule, is frequently inflamed, occasionally the median, ulnar and other nerves. Thomas believes that certain cases of infantile obstetrical paralysis have a similar pathology. A personal case and an analysis of the signs and end results of reported cases are used to support his view. The dislocation with spontaneous reduction or the sprain may be posterior as well as anterior. The pathology of the palsy is the same. Thomas suggests that the same type of injury may underlie some cases of craft palsy. A suggestive case is presented. The acute stage of axillary tear of the capsule without dislocation should be treated for two weeks by immobilization of the arm in full abduction (Codman splint or light plaster) to prevent contraction of the capsule. The arm is then brought gradually to the side and massage and passive motion instituted to aid absorption of inflammatory material and release adhesions. Electrical stimulation is advocated. The chronic stage is best treated by breaking up the resistence under an anesthetic and then employing measures to prevent a recontraction of torn tissues. Operations on the brachial plexus, its roots or its branches, should be deferred until a paralysis from inclusion of the nerves in cicatricial tissue has been eliminated. [T. W. H.]

3. Weber and Dorner present a case of congenital pulmonary stenosis with a careful and interesting study of the accompanying blood changes. The blood showed 10,110,000 reds, 10,275 whites and a hemoglobin of 200% according to the Sahli method. The differential count was normal. Three normoblasts were seen. The viscosity of the blood was greatly in excess of the normal, the coagulability less than normal, the coagulation time being fifteen minutes by the Wright method. This polycythemia they believe to be a conservative one on the part of the bone marrow in order to make up for the diminished oxygenation on account of the congenital heart lesion. [J. B. H.]

1. Osler describes the German system of combining hospital and medical school facilities in what he calls the "hospital unit." He describes the part each factor in the unit should play and urges the adoption of this system in England and America.

5. Riviere urges a more extended use of auto-inoculation in medicine. He first describes the ordinary empirical treatment of many simple conditions by heat, poultices, irritants and counterirritants, all of which he claims are merely examples of bringing about an auto-inoculation. He then goes on to describe how these principles can be further applied to certain respiratory conditions and, in particular, bronchitis. [J. B. H.]

2. Friedrichs describes the new hemoglobin agar media for the detection of cholera germs according to Esch's plan and compares it with other types of media. He considers that this medium and the alkaline blood agar of Dieudonné are superior to the other types of media.

3. Siegheim takes up at length the question of gastric syphilis. It is extremely rare, occurring in not more than 1.5%, if as often. It may occur as an ulceration or as a tumor which may cause pyloric stenosis. The early diagnosis is a very essential feature as the ulcer may go on to perforation, or scar tissue stenosis of the pylorus may occur. The treatment is like that of other forms of syphilis, only using some other route of entry of the drugs if vomiting or ulcer signs occur. The Wassermann test is an aid in diagnosis and in the length of time to continue treatment. [C. F., Jr.

2. The author describes in fullest detail in an article illustrated by diagrams and x-ray plates his treatment for this peculiar gastric disturbance. He quotes from a series of nine cases where he has used his dilator with satisfactory results. The instrument resembles in the main the tube used for washing out the duodenum, save in this respect that a balloon is attached to the tip. This balloon, uninflated, is swallowed and allowed to remain for several hours or, better still, over night. Then it is found to have passed through the pylorus and it is then drawn back into the pylorus and inflated. Einhorn feels that the results warrant its use and offer a hopeful solution of this difficult problem. [J. J. H.]

2. LABBÉ. *Contribution to the Study of the Metabolism of the Ammonia Compounds.*
3. *VAN DEN BERGH, A. A. H. *Hemolytic Jaundice with Hemoglobinuric Crises.*

3. The author gives a detailed account of an interesting case of jaundice which was associated with anemia and attacks of hemoglobinuria. The urine contained no bile pigments, but was always rich in urobilin. The resistance of the red cells was normal, and it was with the greatest difficulty that any lytic action of the serum could be demonstrated. This was produced at last, after a long series of experiments, by the exposure of the material to carbolic acid at a temperature of 37° C. The attacks of hemoglobinuria varied in frequency and intensity, but when at all marked in severity, were associated with an aggravation of the anemia and the jaundice. [J. H. S.]

2. Under this terminology, Maragliano describes a procedure by which a slip, of varying size, from a healthy nerve, with which it remains connected, is implanted into the peripheral portion of a severed or otherwise paralyzed nerve whose function it is desired to restore. He reports a series of animal experiments in which this operation was successfully performed, and from which he concludes that to avoid degeneration the slip for implantation should be not less than half the caliber of the nerve from which it is diverted, should be short, and should traverse a straight, not devious, course; and that suppuration is the most serious complication of such procedures, since it may lead to degeneration and complete motor and sensory paralysis of the sound nerve. [R. M. G.]

## Obituary.

### JAMES CROWLEY DONOGHUE, M.D.

DR. JAMES CROWLEY DONOGHUE, of Boston, who died on Feb. 26 at Georgetown, Mass., was born in Georgetown on Oct. 9, 1864. In 1897 he received the degree of M.D., *cum laude*, from the Harvard Medical School. In 1896 and 1897 he served as medical house-officer at the Massachusetts General Hospital. He was for a time assistant in histology at the Harvard Medical School, and had recently been appointed instructor in hematology at the Tufts Medical School. Dr. Donoghue was formerly a visiting physician at St. Mary's Infant Asylum, and for the past twelve years had served as physician of the Boston Dispensary. He was a Fellow of The Massachusetts Medical Society, a member of the Boston Society of Medical Sciences and of the Harvard Medical Alumni Association. He is survived by his parents and by two brothers.

Dr. Donoghue was a good physician, a hard worker, a helpful teacher, a kind and faithful friend. In his own labors and troubles he never forgot others whom he might be able to assist, and gave to them freely of his time, his encouragement and his friendship. His untimely death will be sincerely lamented by many who thus had come to know and care for him and to appreciate and esteem his character.

## Miscellany.

### MASSACHUSETTS TUBERCULOSIS CONFERENCE.

On Friday of this week, March 3, the third Massachusetts Conference on Tuberculosis is to be held in Boston, at the rooms of the Twentieth Century Club, 3 Joy Street. The purpose of this conference, which was instituted two years ago, is to bring together, for purposes of mutual discussion and study, all those who are interested in the various problems of the work against tuberculosis in this state. The program of papers arranged for the present meeting is as follows:

11 A.M. "Tuberculosis in Children," by Dr. George S. C. Badger, of Boston.

2.30 P.M. "Outline of the Report of the Commission to Investigate and Report upon a System of Caring for Tubercular Patients," by Dr. Arthur T. Cabot, chairman of the trustees of the Massachusetts Hospitals for Consumptives.

"State Subvention to Municipal Hospitals," by Dr. Roger I. Lee, of Boston.

"Material Relief to Patients in Their Homes," by Dr. Julian A. Mead, of Watertown, and Mrs. Ada D. Sheffield, of Cambridge, a member of the State Board of Charity.

## Correspondence.

### "PROPOSED HOMEOPATHIC SANATORIA FOR CONSUMPTIVES."

Boston, Feb. 24, 1911.

*Mr. Editor:* Under the above heading, in your issue of Feb. 16, appeared an editorial which contained so many misstatements of facts that I feel sure, when you find that you have been misinformed, your sense of justice will impel you to admit to your columns a correction of them. Had it been merely a matter of opinion, no attempt would have been made to dispute it.

Your statement that in the sanatorium at Rutland, containing three hundred and fifty beds, there are two services of equal size, is not and never has been correct. The homeopathic service for quite a number of years has contained only about one third of all the patients, as the superintendent and other physicians and nurses and many hundreds of patients, past and present, would testify.

You say, "No patient at this institution has ever made a request for homeopathic treatment." The fact is that for about twelve years, the whole period of its existence since opening (except for a few months lately), an office was kept open in Boston for examinations for admission on two days in the week, and it was publicly advertised by circulars sent broadcast throughout the state that on one of these days those who desired to enter one service should apply, and on the other day those who preferred the other service. A great many, to my knowledge, were pleased to have this privilege of choice. To some, of course, it made no difference.

You say, "As a matter of fact, the treatment given on the two services is absolutely identical." That is a rather strong statement to be made by one who gets his information at second-hand. I will speak only of what I know from actual observation on the spot and can prove conclusively.

For nine years, beginning at its opening, I was in close touch and intimately connected with the work of the institution, as one of the two attending physicians, and as a result of that experience I am very sure that your statement is not true; and I am also sure that all the physicians on both services during that time know and would admit that it is not true. The homeopathic treatment there reflected the prevailing homeopathic treatment outside as nearly as the regular treatment reflected its outside representatives, and the differences between the two were very decided. What is more, we believe that our treatment was more efficacious. This refers only to treatment by drugs, which, of course, we in common with all educated physicians of to-day consider of secondary importance, as compared with hygiene. Naturally the hygienic treatment of the disease is the same on the two sides in every detail, and your very funny but ancient little joke about "administering food and fresh air in homeopathic doses" has no foundation in fact.

Nevertheless, we do believe in the helpfulness of drugs, given symptomatically, and do not despise their aid because some patients now and then get well without them.

You say, "Consumption is a disease treated not by drugs, but by diet and hygiene." I have a large acquaintance with regular physicians, some of them the very best, and I do not know a single one who would be willing to treat such patients entirely without the use of drugs, and I should have very little respect for him if he were so willing. This is so universally recognized that every modern regular textbook and monograph advocates them for the relief of symptoms in addition to hygiene. Kleb's new work devotes fifty-seven large pages to the discussion of the use of one of them alone — tuberculin. Even in spite of the wonderful advance in the treatment of the disease which we have made in recent years, we still fail so often that an honest man will welcome any aid within his reach. If now and then a case comes along with few if any marked symptoms, it may be allowable to trust it to hygiene alone, but the great majority of cases sooner or later need medicinal help. So your great men say and do, and who does not?

By the advice and consent of some of them, the state of Massachusetts has paid out each year for more than twelve years a considerable sum for drugs in its sanatorium at Rutland. Never has any one in the whole medical profession opposed this payment. The last Rutland report which has been printed states the cost of "medicines and hospital supplies" for the year ending Nov. 30, 1909, as $3,696.29. A large portion of this was for drugs alone. Now if it is wrong to treat consumption by drugs, as you say, is not this a pure robbery of the treasury of the state of Massachusetts? Are not the trustees and the physicians to whom they look for advice in matters medical implicated in this robbery? Are the rest of the physicians in the state blameless for not protesting against it? The regulars, therefore, and the homeopathists both prescribe medicine symptomatically in most cases of tuberculosis, but on different principles. At this late day it seems hardly necessary to answer your question as to how they differ.

You say, There is in Massachusetts only one private homeopathic sanatorium for tuberculosis. "Were there a genuine popular demand for such treatment, there would be other such private institutions."

Did you know that the number of *regular* private sanatoria in our state is almost as small, and that the homeopathic one you refer to treats almost as many patients, as all the rest put together? That is so.

You say that last fall we asked for representation in the three new hospitals at Lakeville, Westfield and North Reading, and that now that the trustees have offered us a position in each of these, we refuse them. The fact is we did not ask for this, and the stenographic report of the hearing will bear out this statement. Our appearance was a protest against the separation of the sexes at Rutland, which by sending the men patients elsewhere would deprive them of homeopathic treatment. We asked for a reconsideration of this vote on that and also on general grounds, and as an alternative we asked that we be given a sanatorium entirely to ourselves.

You also say that the homeopathists now ask the legislature for "two sanatoria placed under their entire control, representing, with their share of beds at Rutland, one half the public provision for consumption in the state."

This is not so. We do not want what you say. What we really ask for is only one small sanatorium of one

hundred and fifty beds, instead of our present service at Rutland of almost the same size. This is certainly not an extravagant demand. The present four state sanatoria contain altogether eight hundred beds, and if this legislature builds a new sanatorium, the total will be nine hundred and fifty, of which we ask for only one hundred and fifty, a proportion which is very different from the one half which you say we demand. This would have been obvious to you had you taken the trouble to read our petition to the legislature accompanying the bills. Those acquainted with legislative procedure know that where a petition admits of alternatives, each one of these should be framed as a bill or resolve in form to be passed, if acceptable. It does not mean that all are to be passed; nor does our General Court so understand it.

Respectfully,

HERBERT C. CLAPP, M.D.

## AN ANECDOTE ABOUT CHESELDEN.

BOSTON, Feb. 28, 1911.

*Mr. Editor:* The following anecdote of the famous surgeon, William Cheselden, may not be familiar to your readers.

Lady Suffolk (the celebrated mistress of King George II, of England) was affected with loss of hearing early in life. Cheselden, who was at the time in favor at court, persuaded her that he had hopes of being able to cure deafness by a certain operation on the tympanum, and offered to try the experiment on a condemned convict then in Newgate, who was deaf. If the convict could be pardoned, he would try it; and should he be successful, would perform the same operation on her ladyship. The countess procured the man's pardon, who was a cousin to Cheselden, who had feigned that pretended discovery to save his relation, and no more was heard of the experiment. The man saved his ear, too, but Cheselden was disgraced at court.

Very truly yours,

CHARLES G. CUMSTON, M.D.

## SOCIETY NOTICES.

BOSTON MEDICAL LIBRARY IN CONJUNCTION WITH THE SUFFOLK DISTRICT MEDICAL SOCIETY. — Medical Section Meeting, John Ware Hall, Wednesday, March 15, 1911, at 8.15 P.M. "Some of the Effects of Intense Heat other than Heat Stroke and Heat Prostration." By David L. Edsall, M.D., Philadelphia. Discussion. Light refreshments after the meeting.

EDWIN A. LOCKE, M.D., *Secretary*, 311 Beacon St. HENRY JACKSON, M.D., *Chairman*, 289 Marlborough St.

THE AMERICAN SOCIETY OF MEDICAL SOCIOLOGY. — A meeting of this society will take place at 12 Mt. Morris Park West, New York, on Saturday, March 4, 1911, at 8.30 P.M. sharp. Program: 1. The Reason and Purpose of the American Society of Medical Sociology. 2. "The Rational Limitation of Offspring: the Most Important Immediate Step for the Betterment of the Human Race, from an Economic and Eugenic Standpoint." By William J. Robinson, M.D. 3. Discussion. The discussion will be opened by Dr. A. Jacobi, Dr. S. Adolphus Knopf, Dr. Heinrichstern, Dr. James P. Warbasse and will be continued by other members of the medical profession and the laity.

WM. J. ROBINSON, M.D., *President*. A. C. JACOBSON, M.D., *Secretary*.

NEW ENGLAND BRANCH, AMERICAN DERMATOLOGICAL ASSOCIATION. — There will be a meeting of the society on Tuesday, March 7, at the Boston Medical Library at 8.15 P.M. Paper by Dr. J. Bentley Squier, of New York, "Suprapubic Intra-urethral Enucleation of the Prostate." Discussion opened by Drs. P. Thorndike, B. Tenney, F. B. Lund, A. L. Chute and H. Cabot.

R. F. O'NEIL, M.D., *Secretary*, 370 Beacon St., Boston.

## RECENT DEATHS.

JAMES CROWLEY DONOGHUE, M.D., M.M.S.S., of Boston, died in Georgetown, Mass., Feb. 26, 1911, aged forty-six years.

DR. EMMET DENSMORE, a retired physician of New York, died in Florida, on Feb. 17. He was born at Blooming Valley, Pa., on May 19, 1837, and was graduated from the medical department of the University of the City of New York in 1858.

DR. ALBERT SIDNEY ASHMEAD, of New York, died at the Jefferson Hospital, Philadelphia, on Feb. 20, aged sixty-one years. He was a native of Philadelphia and was graduated from the medical department of the University of Pennsylvania in 1869.

DR. A. O. J. KELLY, of Philadelphia, died Thursday, Feb. 23, after a brief illness. An obituary notice will be published in a later issue.

DR. FLOYD PRESTON SHELDON, who died last week in New York City, was born at Rutland, Vt., in 1858. He studied medicine at the University of Michigan, from which he graduated in 1879. Since 1883 he had practiced ophthalmology in New York. He was a member of the American Ophthalmic Society, of the New York State and of the New York County Medical Society.

## BOOKS AND PAMPHLETS RECEIVED.

Annual Report of the Surgeon-General of the Public Health and Marine-Hospital Service of the United States for the Fiscal Year 1910. Washington, D. C. 1910.

## Original Articles.

# ON THE DEPENDENCE OF INTESTINAL INDIGESTION ON GASTRIC DISTURBANCES.

BY A. R. AUSTIN, M.D.,

*Director of the Clinical Chemistry Laboratory, Mt. Sinai Hospital.*

WHEN Von Noorden proves by carefully conducted experiments in metabolism that nutrition does not suffer in functional or certain organic diseases of the stomach provided that the patient takes sufficient food, since the pancreatic digestion compensates fully for the lack of gastric digestion, he does not take into account, or disregards, the extra burden thrown upon this previous form of digestion; the only exception which he makes, with regard to this maintenance of nutrition, is in those instances where fermentation is the cause of the loss of a large amount of the carbohydrate food in the stomach! We see it often stated that improperly prepared food which enters the intestine causes a catarrhal condition of the same without any absolute proof of this. In the very excellent résumé of this subject by A. Schmidt in the "Pathologie des Stoffwechsels" we find it stated that achylia gastrica or hypochlorhydria is accompanied by a deficiency in the pancreatic juice, while hyperacidity produces the opposite effect. Another author declares that the excessive hydrochloric acid of the increased acid chyme of the stomach, by the destruction of the trypsin, diminishes the activity of the pancreatic juice, with a corresponding emaciation of the patient. Hyperchlorhydria is also stated to produce a constipation which can only be relieved by alleviation of the former condition. The diarrheas which accompany achylias and hypochlorhydria are said to be due to lack of the bactericide action of the hydrochloric acid, but in a former article I have been able to show that the amount of hydrochloric acid in the gastric contents has no effect at least on the indol of the feces, one of the products of intestinal putrefaction of protein material, and this view has been substantiated by many others. Constipation may depend on hyperchlorhydria, but it is undoubtedly due to the better digestion and absorption of the food in the upper intestinal tract, because better prepared when entering the intestine and hence giving less opportunity for the activity of bacteria; in fact, Strassburger has shown that bacteria in feces are much less numerous under this condition, from the lack of nutriment, and not from the greater bactericide activity of the increased hydrochloric acid. As the absorption increases, the residue naturally grows less, and, as Schmidt has shown, constipation results. Apart from this, it is possible, but not proven, that with the increased hydrochloric acid of the gastric contents the neutral reaction of the latter is established so late in its course through the duodenum that its mucous membrane, unprotected against the assaults of an active gastric juice, though fully so against the pancreatic juice, yields before the former and the duodenal ulcer results. Dr. Codman has ventured the possibility that the pancreatic secretion makes its way upward and attacks those parts of the duodenum which are protected against the acid and pepsin, but not against the former; this I think is untenable because in gastro-enterostomy the duodenal content makes its way freely into the stomach, maintaining there continually an alkaline or neutral reaction, yet as far as one can learn from the literature of the subject, duodenal ulcer is not common under these conditions. Then we have the continuous secretion of gastric juice which is much more likely to cause duodenal ulcer, if the latter is due to an active peptic digestion, than the periodical discharge of highly active acid contents into the duodenum at meal time, because the action is more prolonged. So that we may divide our gastric cases for comparison into the achylias, the hyperchlorhydrias and the hypersecretion which exhaust the secretory anomalies for our purpose. As to the atonies or myasthenias and ectasias, due to benign pyloric obstruction, we may say, quoting still Schmidt's article, that "motor, disturbances, whether the delayed emptying of the stomach or the rapid discharge of its contents, have no effect upon the intestine or intestinal digestion and, if such changes of the latter are associated with these conditions of gastric motility, they are dependent upon the allied secretory anomalies, hyperchlorhydria (spasm of the pylorus and delayed discharge of contents) or achylia (rapid emptying). "As to the reverse action of disturbances of intestinal motility on gastric secretion we have the statement of Wiczkowski that diarrhea causes a diminution of the hydrochloric acid of the stomach, while constipation produces its increase, a statement with which Ebstein, from his own experience, cannot agree and which Schmidt doubts; apparently the conditions are associated, but which is primary is as difficult to establish as the precedent of the hen or the egg.

Now, how shall we classify the abnormalities of intestinal digestion, which we may compare with those just mentioned of gastric digestion? Naturally into the two groups of disturbances of secretion and disturbances of motility; but increased intestinal motility is much more dependent on nervous impulses than gastric, and we would make two equally gross errors if we made a coincident gastric disturbance responsible for it, or we made disturbed motility always dependent on actual pathological conditions of the intestine. Nothnagel has especially called attention to instances where diarrhea exists without any perceptible evidence of intestinal catarrh in the form of mucus, and still unabsorbed partially digested food fragments will be found which only with the presence of mucus may mean enteric catarrh. Another function often suffers in the intestinal canal which we are not obliged to consider seriously in the stomach, and that is absorption, a physiological process, again dependent upon complete digestion of the food, on normal motility, or secondarily on that which modifies this motility, intestinal catarrh, nervous

impulse or secretion of bile. Again, apart from the changes of nutrition, which may be infinitesimal, we are obliged to take into account the discomfort of the patient, which may merely consist in interruptions in his business pursuits or social functions, or even in nervous functional diarrheas. The movements may be preceded by colicky pains and loud gurgling sounds. From a large collection of reports of conjoined examinations of gastric contents after a test breakfast, and feces of individuals, largely on a Schmidt diet made for diagnostic purposes, I have selected the following cases to illustrate these conditions. We will first consider the achylias, or, rather, presumably achylias, because while the pepsin is present in some cases, the effect on account of the absence of hydrochloric acid is the same as though no pepsin were present. Of this variety of gastric disturbance there were six cases as follows:

Mrs. T. has diarrhea. Gastric contents: Amount, 15 ccm. No free HCl. Pepsin present. Total acidity, 29.

Stool: Unformed, large number of fatty acid and soap crystals as well as meat fibers. Mucus intimately mixed with the feces with well-stained nuclei free, epithelial cells attached. No connective tissue.

Mrs. D. Constipation. Gastric contents: Amount, 25 ccm. No free HCl. Total acidity, 30.

Stool: In the stool I found no meat fibers or connective tissue, but minute portions of mucus with colored epithelial cells attached, partly digested.

Mrs. K. Long-continued diarrhea. Gastric contents at forty-five minutes showed no free HCl. Stomach empty in an hour after test breakfast.

Stool: Semi-liquid, a large number of fat globules entirely undigested. No meat fibers nor elastic tissue. Numerous minute fragments of mucus intimately mixed with the feces. Many stained shrivelled epithelial cells, whose nuclei have largely disappeared.

Mr. C. Constipation. Gastric contents: Amount, 10 ccm. No free HCl. Total acidity, 14. Rennin present. pepsin not sought.

Stool: Large number of meat fibers and fatty acid needles. Large number of shrivelled stained epithelial cells with nuclei obliterated by digestion. No mucus.

Mr. E. Constipation. Gastric contents: Amount, 29 ccm. No free HCl. Rennin and pepsin present.

Stool: Dark, formed and covered with tenacious mucus not mixed with the feces. No food elements whatever. Few minute fragments of mucus which are stained, but no cells imbedded in same. No elastic tissue.

Mrs. G. E. K. Diarrhea, two to three movements daily. Gastric contents: Amount, 30 ccm. No free HCl. Total acidity, 5.

Stool: Liquid, of light yellow color. Large number of well-stained meat fibers. Very many fatty acid crystals. Elastic tissue, many fragments of stained mucus mixed with feces.

Of these six cases, it is seen, only three had diarrhea which is supposed to accompany achylias, and in but one instance is connective tissue a feature in the stool. Fatty acid crystals, however, are pretty constant and meat fibers form a large portion of the microscopic picture; these are undoubtedly dependent upon the increased motility of the small intestine, which is unquestionably associated with an increased gastric motility, as indicated by the invariably small amount of contents withdrawn and by the fact that in one case (Mrs. K.) it was necessary to withdraw the contents at forty-five minutes, since the stomach was empty in an hour. In three cases the mucus found was of such a nature as to indicate that it came from the small intestine (small stained fragments intimately mixed with the feces), while in one case the mucus undoubtedly came from the colon. This condition does not by any means necessarily indicate an inflammatory disturbance of the intestine, for, as in asthma, mucus can be secreted from nervous impulse alone and, when secreted by this influence in the bowel, by subsequent digestion affords exactly this appearance. The symptoms in all these cases would seem to confirm this suspicion of the neurasthenic character of this form of disorder. Patients complain of "bowels distended with gas," "throbbing in the legs," "legs numb above the knees on standing," "has a dazed feeling," expressions which are taken at random from the history of these patients. One thing is very noticeable — that we do not find elastic tissue which Schmidt describes as accompanying these achylias, and so common is this difference from that author's dictum that I no longer attempt to diagnose a diminution of hydrochloric acid from the discovery of elastic tissue in the stool. In other words, it is not found where hydrochloric acid is wanting and is found, sometimes, where hydrochloric acid is in excess. Another noticeable factor with reference to these patients is a small amount of gastric contents withdrawn. This only substantiates the observation often made that achylias are associated with increased motility, and in spite of the discovery of Pawlow that gastric juice may be secreted by the mere impression of taste and sight of food which arouse appetite, it is not improbable that in purely functional forms of disorder, were the food to remain longer in the stomach, active gastric juice would be secreted; nor is it probable that this increased motility is confined to the stomach alone, but is participated in by the small intestine, thereby producing in the feces the evidences of intestinal indigestion; this seems much more probable that that there is any failure or deficiency in the pancreatic juice, since of its three functions, digestion of fat, protein and starch, the two former are most commonly faulty.

We will now proceed to the other extreme, where we have five cases of hyperchlorhydria, which I prefer, for purposes of analysis, to differentiate from hypersecretion, though Bickel would have us understand that they are one and the same.

Mr. E. C. Bowels regular. Gastric contents: Amount, 75 ccm. Free HCl, 95. Total acidity, 115. Five subsequent examinations in which the free HCl varied from 55 to 90.

Stool: No abnormalities found.

M. M. Diarrhea, two to three loose stools daily. Gastric contents: Amount, 45 ccm. Free HCl, 50. Total acidity, 78.

Stool: Semi-solid, unformed, with no mucus adherent. Numerous well-stained meat fibers, moderate amount of neutral fat and some soap crystals. Very many stained and unstained epithelial cells, some with nuclei.

C. H. Constipation alternating with diarrhea. Gastric contents: Amount, 70 ccm. Free HCl, 75. Total acidity, 95. Two other examinations were made where the free acid was 80 and 56 (treatment by olive oil?).

Stool: Formed, hard, containing scybalæ. Numerous meat fibers, small amount of free fat and a few fatty acid needles. Some small fragments of mucus to which a few stained epithelial cells were attached.

W. T. Constipation. Gastric contents: Free HCl, 60. Total acidity, 70.

Stool: Black, hard and formed. A few well-colored meat fibers and fatty acid crystals; a very large number of small fragments of mucus with many colored epithelial cells imbedded therein. There was also some elastic tissue.

E. J. Bowels regular. Gastric contents: Amount, 120 ccm. Free HCl, 55. Total acidity, 65.

Stool: Semi-solid, normal color. Numerous fatty acid needles and well-stained meat fibers. Large fragments of mucus from the colon (colorless cells with nuclei) as well as minute fragments (microscopic) of mucus, highly colored and well mixed with the feces containing many nuclei-free epithelial cells; many so-called "sago" grains.

It will be readily seen that constipation is not a constant concomitant of hyperchlorhydria. In these five cases it occurs once alone and once alternating with diarrhea; in one other case diarrhea was constant, and twice the bowels were regular. Three of these cases showed mucus in the feces of the minute variety, which indicates its origin from the small intestine. This source is still further substantiated by the attached colored cells which were found. The question naturally arises, Is the mucus due to a true inflammatory disturbance or to a neurosis such as is found in asthma? Probably the latter, since in none of these cases is tenderness of the abdomen complained of, and the symptoms are referred almost wholly to the stomach. In every case, too, where only a functional disturbance of the intestine occurs, digestion of meat and absorption of fat are impaired; now, as meat fibers and fat are digested by the pancreatic juice, this disagreement in its function is hardly probable as a result of impairment and, as mentioned, the incongruity is dependent upon increased motility in the small intestine, which, with Bickel's view that hyperchlorhydria is dependent upon the increased motility of the stomach, makes a consistent whole of the hastened activity of the gastro-intestinal tract, or at least of that part of it involved in digestion and absorption. The presence of elastic tissue with a free hydrochloric acid of 60 requires some other explanation than that of ineffective gastric juice, if the old view that increased hydrochloric acid is associated with increased pepsin prevails. Schmidt states that, if this occurs (presence of elastic tissue) where the motility is impaired, it must be associated with diminished pepsin, which, he states, may occur with the increased normal acid of the stomach.

There are now two cases of hypersecretion that have been selected from the list which are introduced largely for comparison.

E. P. Constipation. Gastric contents: Amount, 270 ccm. Solid portion, ¼. Free HCl, 25. Total acidity, 41.

Second examination: Amount, 225 ccm. Free HCl, 35. Total acidity, 55.

Stool: Scanty, solid and of light brown color. Some neutral fat and abundant fatty acid crystals. An occasional well-stained meat fiber but no starch. Many small fragments of mucus, well studded with colored epithelial cells.

J. K. Constipated. Gastric contents: Amount, 120 ccm., one quarter solid. Free HCl, 55. Total acidity, 70. Twelve hours after eating a Riegel test meal, 20 ccm. of fluid expressed containing no food fragments but having a free HCl of 40.

Stool: Hard, formed, contains a few fat globules but no fatty acid and no mucus.

In the group of cases of which these two form an example there can be no possibility of an impaired motility, either exaggeration or delay, so that we have to deal with a pure secretory anomaly and find that in one case there is impairment of intestinal digestion and in the other not.

Now, we come to a group of cases where impaired motility is assured, for these are clearly not instances of obstruction at the pylorus; rigidity of the stomach did not occur in any case and the stomach was able to empty itself fully but after a prolonged period. The stomachs were all dilated, reaching to the navel, or below, on inflation.

T. P. Constipation. Gastric contents: Amount withdrawn, 240 ccm., two-thirds solid. Free HCl, 60. Total acidity, 75.

Stool: Mushy stool of brown color; a small amount of free fat and starch granules present. A few lightly stained meat fibers and a vast number of fatty acid and soap crystals. Numerous shreds of colored mucus with colored epithelial cells attached and a few connective tissue masses.

C. R. Constipated. Gastric contents: Amount, 240 ccm., one-half solid. Free HCl, 75. Total acidity, 100.

Stool: Brown and formed. No mucus attached. Microscopically a large number of free starch granules and a great many fatty acid crystals. Very many minute fragments of mucus both colored and uncolored with cells attached. No connective tissue.

M. Mc. Constipation. Lower border of stomach normal, but succussion two hours after eating. Gastric contents: Amount, 120 ccm., one-third solid. Free HCl, 45. Total acidity, 60.

Stool: A hard formed stool with some mucus attached. No fat, starch nor meat fibers. Upon examination the mucus was found to be colorless (colon) and free from attached cells.

S. P. Constipation. Gastric contents: Amount, 150 ccm., one-half solid. Free HCl, 50. Total acidity, 70. Nine and one-half hours after a meal of scraped meat, a slice of bread and 240 ccm. of milk, 60 ccm. of gastric contents was withdrawn from the stomach, of which two-thirds was solid, with a free HCl of 35 and a total acidity of 50.

Stool: Light colored and semi-solid. Many minute fragments of mucus without epithelial cells adherent and connective tissue. No meat nor starch, but many soap crystals.

In these cases it is interesting to note the presence of connective tissue as a constituent of the stool in two instances where the HCl is ample; in fact, in one case much increased (60); what, then, is the cause of their presence if elastic tissue is always digested in an active gastric juice? Here we do not have the excuse of a hastened motility, for plainly such does not exist in these patients. Schmidt offers the rather lame explanation that where the motility of the stomach is impaired, decomposition agencies (*Zersetzungprocesse*) play their part, but such processes are never prominent where free HCl is present in normal quantities, much less so when in increased amounts, as in most of the cases reported. My own explanation, though theoretical, is based upon sound physiological principles. Motility of the stomach is largely confined to the pars pylorica, and while thorough mixing of the food occurs there normally, it has been demonstrated by sections of a frozen digesting stomach that the food remains in the fundus of the stomach in consecutive layers in which only the outer portions come in contact with the stomach wall and hence with the active gastric juice. Therefore with impaired motility of the pyloric portion of the stomach it is conceivable that the connective tissue of the test diet may pass through the pylorus without coming in contact with the gastric juice. That deficient pepsin may occur with increased HCl has been proven, but it remains for some one to prove that this is the cause of the presence of connective tissue in the stools when hyperchlorhydria is present. In two instances we find in the stool minute fragments of stained mucus with epithelial cells attached, which are usually deprived of their nuclei by the action of the trypsin; we have agreed to call this condition functional enteric catarrh to distinguish it from the true enteritis which is usually associated with diarrhea; but as is well known, we may have a fairly marked enteritis with constipation, or constipation with alternating diarrhea, since, with lack of involvement of the colon, the liquid intestinal contents hurried through the small intestine have an opportunity to "dry out," so to speak, beyond the ileocecal valve by delayed passage and absorption of water so that the movements may occur but once in a day or even once in two days, be hard and formed and still contain mucus, which unquestionably comes from the small intestine. This condition is no more strange than that found in typhoid where with unquestioned inflammation of Peyer's patches the movements occur only by means of artificial aid. In three instances the presence of fatty acid and soap crystals shows the lack of absorption; in fact, absorption seems to suffer more than digestion in these functional disturbances of the small intestine, for their presence demonstrates the perfect digestion of fat provided no fat globules are present. True, we may have partial splitting of the fat by bacteria, even if pancreatic juice be wanting in the intestine, but in over two hundred examinations of stools, I have never failed to find some free fat in conjunction with the fatty acids where we had reason to suspect the elimination of the pancreatic juice from the intestinal canal. In two instances also, where resource was had to rectal feeding in which fat was employed, often after twelve hours' retention of a nutrient enema, though in the stools fatty acids were numerous, still some unsplit fat remained. In two cases of this series there was evidence of impaired intestinal digestion, in one case of both fat and starch and in the other of starch alone. We must attribute these anomalies, as before, to increased motility of the small intestine since we cannot conceive of an absence of the pancreatic juice without all its digestive functions suffering. Why this increased motility should affect the starch and protein digestion more severely than the fat is unexplainable, but such is usually the case. In laboratory experiments fat is not split any more rapidly than starch is converted to its digested products, but protein requires the greatest amount of time for its complete conversion. It is time we should all begin to recognize this fact to which Nothnagel pointed many years ago, that well-marked idiopathic intestinal catarrh confined to the small intestine may exist with daily formed stools and this condition can only be detected by careful microscopical examination. True, such individuals may have intercurrent diarrheas of short duration which, while the author mentioned ascribed them to errors in diet, I am inclined to attribute to mere mental strain or effort, as, for instance, an unusually trying day's work. Such cases differ very decidedly from the ordinary diarrhea due to mental influences without the antecedent chronic catarrh; the stools in the former instance are liquid, may contain the food elements and even bile and mucus, but they are not filled with desquamated epithelial cells, particularly those which show granular degeneration.

In conclusion, we may say from a study of these cases that diarrhea does not always accompany an achylia nor a hypochlorhydria, nor, from the presence of connective tissue in the stool, can we always deduce the state of the gastric juice. Furthermore, while hyperchlorhydria is usually accompanied by constipation, we may have diarrhea, or the bowels may be regular, while with gastric myasthenia constipation is the rule, as it is in hypersecretion. A functional chronic catarrh of the small intestine may exist associated with any of these gastric conditions, with excessive or no free HCl and with increased or impaired motility, so that we can only say that improperly prepared food is poured into the small intestine which either on account of this extra burden or on account of some antecedent inflammatory disturbance undergoes a functional impairment that usually manifests itself by the increased motility.

## ON THE POSSIBLE EFFECT UPON THE AUDITORY LABYRINTH OF THE EHRLICH-HATA REMEDY IN THE TREATMENT OF SYPHILIS.*

BY PROF. G. ALEXANDER, M.D., VIENNA, AUSTRIA.

TRANSLATED WITH THE AUTHOR'S PERMISSION BY GEORGE L. RICHARDS, M.D., FALL RIVER, MASS.

PROFESSOR FINGER recently reported three cases of syphilis in which there appeared peculiar and somewhat serious symptoms affecting the organs of hearing. It must, therefore, be our most diligent study to determine as early and as surely as possible, whether, in the presence of such symptoms, we have to do with the poisonous action of the arsenobensol upon the auditory nerve or not. I may be able to contribute some material which will aid in the clearing up of this question. For a period of six years I have constantly collected clinical and, as far as it was possible, anatomical material for the study of syphilitic diseases of the ear, and this material is for the most part already prepared for publication in the "Handbook of Genital Diseases."

Up to the year 1907 my material consisted of all those cases of syphilis which for purposes of diagnosis were sent from the two dermatological clinics of the Vienna General Hospital to the Ear Clinic. Through the kindness of my colleagues of the Policlinic, privatdocent Dr. Nobl and privatdocent Dr. Brandweiner, I have had the opportunity to observe all the cases of syphilis appearing there since 1907. During the years 1907–1908 I also had the opportunity of examining the material from the clinic of Professor Finger. This gave me the opportunity to observe and diagnose those forms of disease of the ear, and especially of the auditory nerve, which give so few symptoms, and these so rapidly disappearing, that the patient does not usually apply for treatment. For this reason such ear symptoms are easily overlooked. Finally, my material consists also of those cases in which the patient complained of trouble in the ear either at the time of or since the syphilitic infection that have applied for treatment at the ear department of the Policlinic since 1907.

A short time before the paper of Professor Finger was published he asked me the following important question, "Before we had the Ehrlich-Hata remedy '606' you had for a long time the opportunity to observe, and to methodically examine, my clinical material. Have you seen during this time any cases similar to those which I observed after the use of the injection?" This question I now answer. My observed material of syphilis of the ear, excluding those cases of diseases of the ear metaluetic in character (i. e., of tabes and paralysis), consists of sixty-eight cases. These have all been thoroughly examined and observed for quite a long time so that I am able to draw conclusions of both diagnostic and prognostic significance. In the course of the last six years I have seen twelve cases of ear disease appearing in the early stages of syphilis. Three of these cases showed disease of the external and middle ear, but in comparison with the cases reported by Professor Finger and Professor Urbantschitsch they show less severe affections of the auditory nerve and are, therefore, to be excluded. Comparing, now, my remaining nine cases with the three of Professor Finger, I obtain the following results. My nine cases represent a period of observation of six *years;* the three cases of Professor Finger of six *months*. In one of Professor Finger's cases the syphilis was of six weeks' duration; in the other two it was of three months' duration. Among my nine cases I can only find one in which the ear disturbance developed after thirteen weeks. In all the other cases in which the disturbance of hearing came during the early stage of the syphilis, it did not appear earlier than the fourth, fifth or sixth month.

We will now compare them as regards severity. Four of the cases showed a very slight degree of disturbance of the auditory nerve, slight dizziness or a slight degree of deafness, with subjective noises and a rapid favorable result. Serious or severe ear disease, as in Professor Finger's cases, I have observed in only five of my cases. One of them was treated with atoxyl; in the other four the symptoms appeared after the ordinary forms of mercurial treatment by inunction or injection. From this it follows that acute syphilitic neuritis of the auditory nerve, whether localized in the cochlear or vestibular portion of the nerve, is, in the early stages of syphilis, very rare. During a period of six years, and with a much larger material, I have seen only *one case more* (5) with vestibular symptoms than has Professor Finger with his arsenobensol-treated material during six months. In the literature up to the present time, cases of labyrinth syphilis, i. e., syphilitic inflammation of the auditory nerve in the early stages of syphilis, have been almost unknown. In his book on Ménière's symptom-complex, Von Frankl-Hochwart surveys forty cases of syphilis. The symptom-complex of Ménière is nothing else than a disease of the labyrinth or the vestibular nerve, and the entire forty cases of Von Frankl-Hochwart are those of chronic or latent syphilis. Professor v. Frankl-Hochwart has told me that he has never observed the Ménière symptom-complex in an early stage of syphilis. Politzer has reported the appearances of labyrinth syphilis in one case of syphilis of seven days' duration. This observation was made in 1878 and is, up to the present time, unique.

From the foregoing it is certain that the cases reported by Professor Finger, in so far as they are cases of disease of the auditory nerve in an early stage of syphilis, must be considered to have an etiological relation to the arsenobensol. It is not yet possible to assume with absolute certainty if during antisyphilitic treatment severe labyrinthine symptoms appear, that such symptoms are of necessity due to the treatment. Should one, however, defend this assumption, he must admit that it is possible to have, as

*A paper presented before the Gesellschaft für Aerzte, Vienna, Dec. 6, 1910.

Professor Riehl has rightly pointed out, severe cases of Ménière's symptoms, the severe acute forms of auditory nerve disturbance, even absolute deafness after or during the usual mercurial treatment. Among my material I recall two such cases, in both of which severe Ménière's symptom-complex appeared during the usual mercurial treatment. Both were, however, as are the other cases in the literature, cases of long-standing syphilis.

I now come to the consideration of my own observations on patients treated with arsenobenzol. These observations are based on the cases of syphilis treated by privatdocent Dr. Nobl, with arsenobenzol, seventy-two in number. Regarding the other peculiarities of his observations he has already spoken. Of the seventy-two cases, there was only one in which, after the injection, symptoms of disease appeared in the organ of hearing.

The patient was a seamstress thirty years of age who acquired syphilis in the spring of 1910 and had injections of mercury. At the end of July disturbances of hearing appeared in the right ear. She complained of deafness and disagreeable tinnitus, increased by movements of the head. Dizziness was also produced by movement of the head and she had the feeling as though something was turning inside the head; she staggered toward the right side but did not observe any turning of herself or apparent rotation of the surroundings. She had neither nausea nor vomiting. There was at this time some disturbance of vision in the right eye. The patient came to my clinic early in August. Examination showed disease of the right auditory nerve in the cochlear as well as the vestibular portion. At this time the left ear was absolutily normal. Under treatment by Dr. Von Zumbusch in the Rudolphspital the right-sided ear affection completely healed. She heard perfectly well in each ear and remained free of all symptoms until Oct. 2. On Oct. 16 she came to the clinic with the history that the right ear had remained completely healed but that on the afternoon of the 2d of October she suddenly noticed that she heard badly in the left ear and at the same time severe noises appeared. Examination at this time showed the right ear to be normal in every way while the hearing power of the left ear was greatly diminished (cochlear affection), but there were no vestibular symptoms to be attributed to the left side. The same day, Oct. 16, she received from Dr. Nobl an injection of the Ehrlich-Hata "606." After the injection the noises in the left ear stopped; she thought also that she heard better in the left side. Several days later sharp pains in the left ear came on, these extended down the neck and on to the back of the head and have continued up to the present time (Dec. 6) almost unchanged. On rising on Nov. 10 she noticed that she heard very badly in the left ear, and the noises were as bad as in the beginning. On her way to the Polyclinic she had a severe attack of dizziness so that she very nearly fell to the ground; articles about her seemed to turn to the right and she has had more or less dizziness since. On this date there was also some fever. Since Nov. 11 she has vomited two or three times daily. The dizziness is increased by changes of position, the attacks becoming paroxysmal on standing up or lying down, while during complete rest there is occasional freedom from the dizziness. Examination of the ear on Nov. 11 showed that the originally diseased right ear remained absolutely normal; on the other hand, the left ear had completely lost its function and the vestibular apparatus and the vestibular nerve did not react. This condition remains now, Dec. 6, unchanged. Since the middle of November there is also present a paralysis of the left facial nerve in all three branches. The paralysis is not complete, and the reaction to the faradic current still remains.

We have here a clinical picture under observation from the very beginning, as the patient before the Ehrlich-Hata injection had already, in the early stage of the syphilis, symptoms of disease in the inner ear of the right side. These symptoms affected the right ear only, and after treatment by mercury they entirely disappeared and complete healing took place.

Later, however, although still in the early stage of the syphilis, similar symptoms appeared in the left ear and became very much worse after the Ehrlich-Hata injection. Following this injection the disease extended itself over the entire area of the left auditory nerve and finally resulted in deafness and complete loss of function in the labyrinth of that side.

I think this case is suitable for bringing to our understanding the part which the arsenobenzol played as the etiological factor in the production of the ear disease. It is important to notice that the arsenobenzol was given at the time when the left auditory nerve was acutely diseased. In my opinion the previously existing disease of the vestibular nerve presented *a point of weakened resistance to the action of the arsenobenzol.* The right auditory nerve, which was healed at the time, was not affected, but the left, already diseased ear was made much worse after the injection; hence we come to the conclusion that in cases of recent syphilis where there is already disease of the auditory nerve there is danger that the disease of the nerve will be made much worse by the use of the arsenobenzol.

Further observations will be necessary to determine whether this danger exists only in the presence of already existing syphilitic disease of the auditory nerve, as in my case, or whether an already existing non-syphilitic disease of the auditory nerve affords a predisposition or probability that the disease of the nerve will be made worse by the use of the arsenobenzol.

When one considers the experiments made with arsazetin, it seems probable that there is some danger of making the condition worse in every case in which at the time of the arsenobenzol injection there is already present disease of the auditory nerve, whether syphilitic or otherwise.

Ehrlich produced, by injecting white mice with arsazetin, phenomena similar to those of the true Japanese dancing mouse, Röthig has examined the central nervous system of the arsazetin-injected mouse after the plan of the work of Kreidel and myself on the ear of the Japanese dancing mouse. As an anatomical basis for the dancing movements of the arsazetin-injected mouse he found degeneration of the central fibers of the vestibular nerve. In order to answer the question why, apart from the optic nerve, the arsazetin finds its point of attack in the vestibular nerve in the white mouse, he examined the vestibule nerve in a larger number of normal white

mice. He found that in the white mouse there was already beginning a certain amount of vestibular degeneration. The arsazetin finds, therefore, in the vestibular nerve of the ordinary white mouse, a point of lessened resistance. This explains, according to Röthig, why, after the arsazetin injection, there appears at once in the white mouse a severe degeneration in the vestibular nerve and at the same time a disturbance in the turning movements. From these conclusions we come to the following theory. It is not to be expected that a previously sound auditory nerve will be destroyed by the arsenobenzol injection. On the other hand, an unfavorable action from the arsenobenzol is to be feared whenever the auditory nerve is diseased previous to the use of the arsenobenzol.

Finally, I wish to state my own standpoint as an otologist with reference to the manner of the action of arsenobenzol upon syphilitic ear patients. More and more often is the question asked whether, in a case of syphilitic ear disease, the Ehrlich-Hata injection is indicated or not. After the preceding observations, which naturally do not give an absolute finding, it is to be recommended to use caution in cases of acute syphilitic disease of the auditory nerve. Especially is caution in the use of the remedy to be recommended in the presence of acute or chronic disease of the auditory nerve in cases of recent syphilis, as here it is to be feared that the ear symptoms will be made worse. It appears to make no difference whether the disease of the auditory nerve is of itself of syphilitic origin or not.

An unfavorable influence is also to be feared in cases of acute syphilitic affection of the auditory nerve in old cases of syphilis or latent chronic syphilis. In cases of hereditary syphilis it is also to be recommended in the presence of acute manifestations of trouble with the auditory nerve to wait before giving the Ehrlich-Hata injection.

On the other hand, there are a large number of cases of ear disease in which the previously described dangers from the arsenobenzol injection cannot be considered as dependent upon it. Here belong the cases of chronic syphilitic affection of the auditory nerve with slight diminution of hearing power and considerable tinnitus, as well as the cases of chronic labyrinth dizziness. I would only mention that in these cases we had good results from treatment before the time when "606" achieved good results.

Finally, the Ehrlich-Hata has a good effect in cases of chronic labyrinth disease in chronic syphilis. The good results reported by Professor Urbantschitsch in one case of hereditary syphilis and in two cases of cochlear disease and chronic syphilis encourage us to proceed farther along the path already laid out.

NOTES BY THE TRANSLATOR.

The three cases of Professor Finger to which reference is made were those cases out of 170 treated with "606" which showed ear symptoms after the injection.

Case I, male, twenty-two years, came to *klinik*, Aug. 20, 1910, with cutaneous syphilis and osteoperiostitis of the tibia. Aug. 24, 0.5 neutral Ehrlich-Hata injected. Aug. 25, nystagmus, dizziness, typical falling symptoms, but with intact hearing. Diagnosis by the Ear Clinic: Isolated disturbance in function of the vestibular nerve. Complete recovery in a few days.

Case II, male, twenty-five years of age, syphilis six weeks. Aug. 27, 1910, 0.45 Ehrlich-Hata, method of Wechselmann, injected. Sept. 8, initial lesion healed, patient discharged. No sign of secondary syphilis up to Nov. 2, and Wassermann negative. On this date, nine weeks after the injection, and three months after the infection, dizziness and deafness appeared. At the Ear Clinic the diagnosis of bilateral labyrinthine deafness was made. The condition remains unchanged.

Case III, female, eighteen years, came Aug. 1 for macular type of syphilis of three months' duration. Aug. 5, 0.45 neutral Ehrlich-Hata, method of Wechselmann, injected. Aug. 17, all signs of syphilis had disappeared and she was discharged cured. On Nov. 3 she was free from syphilis. Wassermann reaction negative. Nov. 3, complained of dizziness, headache, and the Ear Clinic made a diagnosis of labyrinthine deafness, dizziness and spontaneous nystagmus. There is no improvement at time of reporting, Nov. 27, 1910. (Wien. klin. Wochenschr., No. 47 and No. 51, 1910.)

At a subsequent meeting of the Gesellschaft für Aerzte in Vienna, before which Professor Finger's paper was read, some other cases in addition to those of Professor Alexander were reported where ear disease had appeared as late manifestations after the use of the Ehrlich-Hata.

v. Zumbusch had found in the literature, among 7,000 cases from twenty-five *klinikz*, 9 cases of auditory nerve disturbance, all being cases with secondary manifestations from second to seventh month, and in most cases the Wassermann was negative.

Dr. H. Frey reported a patient injected on Aug. 9 with 0.5 arsenobenzol who returned late in October with deafness and some vestibular nystagmus. This case later showed the exanthemata of syphilis so that Dr. Frey was not certain that these manifestations could be laid to the arsenobenzol. (Wien. Klin. Wochenschr., No. 50, 1910.)

Through the kindness of Dr. Daniel Kaufmann, I was given the opportunity of seeing two cases, each of whom had deafness and labyrinthine symptoms some time after the Ehrlich-Hata injection. At the time of the appearance of these symptoms the Wassermann reaction was positive. Both patients were given mercury by injection, and when I saw them all symptoms were improving. Here it might be difficult to say whether the ear symptoms were due to the arsenobenzol or to the uncured syphilis. In Dr. Kaufmann's opinion they were due to the arsenobenzol.

Professor Rille, of Leipzig, has recently reported (Berl. klin. Wochenschr., Dec. 12, 1910) three cases of ear involvement which may be briefly referred to:

Case I, female, twenty-one years old, with no previous ear symptoms, maculo-papular syphilide with involvement of the tonsil, was given an injection of Ehrlich-Hata, July 7, 1910. Four weeks after the injection, 0.45 gr., there appeared, dizziness, noises in ear and deafness located largely in the right ear, where both air and bone conduction were lost. Later there appeared a partial facial paralysis and symptoms of choked disk in the right eye. Up to Nov. 15 there had been some improvement, there is some bone conduction, but conversation speech is not heard. The left ear is normal.

Case II, female, eighteen years old. Ehrlich-Hata injection, 0.45, on July 10. On Oct. 10 pain in head

and dizziness appeared and on the following day right-sided facial paralysis, followed in three days by optic neuritis. Under treatment with mercurial ointment the facial paralysis and other symptoms disappeared. Nov. 17, discharged cured.

CASE III, male, thirty-three years old. Injection of 0.7 Ehrlich-Hata, July 7. In middle of October there suddenly appeared a high degree of double-sided labyrinthine deafness at which his previous occupation, that of blacksmith, may have predisposed.

## THE TREATMENT OF FISTULA IN ANO.*

BY T. CHITTENDEN HILL, M.D.,
*Surgeon to the Rectal Department of the Boston Dispensary, Boston, Mass.*

MY reason for bringing to your consideration such an old subject is that the operative treatment of ano-rectal fistulæ involves several interesting anatomic questions.

Besides, it is the most common of rectal troubles, constituting nearly 50% of rectal affections, and the results of improper treatment are so direful and manifest that it may prove profitable to review briefly the best methods of procedure in the more common varieties of fistulæ.

There are two methods more or less in vogue at the present time that are so enthusiastically recommended by their advocates that I would like to refer to them briefly, even though they do not seem to me to possess much merit.

They are, excision with immediate suture, and the treatment by the injection of bismuth paste.

### (1) EXCISION WITH IMMEDIATE SUTURE.

This method, as a refinement of surgery, has been recommended as the ideal operation, and it would seem that we must instantly and unhesitatingly decide in favor of it.

All are agreed that the method is ideal, but practically it is almost impossible to so sterilize a fistulous tract as to get primary union, and I have yet to know of any surgeon who has practiced this method for any length of time not to come to the same conclusion.

It is one of the first principles of surgery to drain an abscess, and a fistulous tract is nothing more or less than an old contracted abscess cavity.

Of course, in a simple direct fistula without lateral burrowing, the whole tract may be dissected out and sutured with some prospect of a perfect union, but these fistulæ are so simple and small that it is hardly justifiable to confine the bowels and the patient as well for five or six days, when they can be just as quickly and with less inconvenience cured by a simple incision.

### (2) INJECTIONS OF BISMUTH PASTE.

The injection of a bismuth vaseline paste stiffened somewhat with paraffine was first advocated by Dr. Emil G. Beck, of Chicago, for the treatment of chronic sinuses and fistulæ. It was thought that the curative agent lay in the nitric acid which was given off by the hydrolizing action of the heat of the body on the subnitrate.

* Read before the Norfolk District Medical Society, Dec. 27, 1910.

Although Beck had used it more especially in other parts of the body, a prominent surgeon soon reported seventeen cases of rectal fistulæ, 75% of whom were apparently cured.

The phrase "apparently cured" is rather ambiguous, as a rectal fistula is either cured or not cured, as any one can demonstrate for himself.

In a recent paper, however, this same authority states that later results were not so favorable, and continues as follows: "Formerly I treated all my fistula cases with the paste; now I select them and am having better results."

The technic, which is quite simple, is to first liquefy the paste by heating in a water bath and then with a suitable syringe inject with sufficient force to fill all the tracts and diverticuli of the fistula.

The internal opening, if one exists, is plugged with the finger in the rectum, and other external openings are kept closed by an assistant.

These treatments are to be continued at intervals of three or four days. The paste is supposed to come out spontaneously in from twenty-four to forty-eight hours, but in one of my cases — a blind external fistula — such was not the case. As the patient complained of considerable pain after two weeks' treatment, a digital examination was made and a retrorectal abscess could be felt three inches above the anus.

An operation was at once performed under general anesthesia, and upon laying open the original sinus, a hard mass of the paste, the size and shape of a small English walnut, was found, which without any doubt, by blocking up the discharge, had been the cause of the abscess higher up.

By making a free T-incision the abscess and fistula as well were cured without further complications.

My experience with the paste has been limited to twelve dispensary patients, upon whom I employed this method, giving much attention to the details of administering it, but I am unable to report a single cure.

Numerous other proctologists who have used the bismuth paste report similar results, or at the most claim only to have met with partial success.

For this reason I believe this method will ultimately go the way of the elastic ligature, the injections of caustics and others; that the incision operation is to-day, has been in the past and will in all probability for some time to come, remain the procedure most suitable for the majority of fistulæ.

### (3) INCISION.

I wish simply to emphasize certain well-recognized principles of this operation, the neglect of which by the surgeon has often led to failure and laid the operation open to criticism.

Tuttle's statistics of 2,196, collected from the records of general hospitals, reveal the disquieting fact that only 45% of the cases treated are claimed to have been cured, and it must be remembered that these are the statistics of the experienced

surgeon operating under favorable environment rather than the occasional operator, who is frequently obliged to do his work under less favorable surroundings.

The general rules applicable when operating upon any form of fistula are well known to most of you and need only be mentioned in this brief paper. It should never be forgotten that all manipulation with probes should be carried out with gentleness so as not to make a false passage. Especially is this true when operating within the rectum, as a steel director roughly used will easily pass through the submucous tissue, leading one to divide sinuses which are only the result of the surgeon's bungling. All subcutaneous burrowing should be laid open for a half inch beyond its extreme limit.

When there is difficulty in finding the internal opening, all the external lateral burrowing should first be dealt with, after which the main tract will be apparent and the internal opening easily found.

Overhanging edges of skin, especially if discolored or undermined, should be trimmed away.

Redundant mucous membrane abutting on the line of incision should be excised, or, if very vascular, ligated in the same manner as internal hemorrhoids.

These are general rules recognised by all surgeons and more or less regularly adhered to.

Aside from them, there are certain other interesting points upon which the success or failure of an operation depend.

In discussing these questions I ask your indulgence if many statements seem dogmatic, as it is believed they present the concensus of opinion of those surgeons who have had the most experience in treating this disease.

*First:* What are the dangers of incontinence? There is no disputing the fact that this condition does occur following fistula operations, but not with anything like the frequency that is generally attributed to it by the laity or the profession.

It is in nearly every instance preventable if proper regard for the sphincter be had during the operation and if, during the after-treatment, the wound be loosely packed and the skin and mucous membrane prevented from growing down into the incision. A fistular wound should never be packed, and if the words "packing" and "plugging" in this connection were eliminated from the works on general surgery, there would be less incontinence.

Now about injury to the sphincters. These muscles have been said to be the most important of the whole body, for if their office is destroyed by trauma or disease, the person is rendered miserable for life. Guarding the anal orifice is the external sphincter, a flat plane of muscular fibers elliptical in shape, intimately adherent to the skin which surrounds the anus, attached posteriorly to the coccyx by the ano-coccyxigeal ligament and terminating anteriorly in the central point of the perineum.

It is a voluntary muscle supplied by a branch of the fourth sacral nerve.

The internal sphincter is a thin muscular band half an inch in breadth, and but an aggregation of the terminal circular fibers of the intestine, and is not subject to volition as is the external. It is overlapped by the external sphincter.

Although authorities are not absolutely unanimous on this point, it is very generally conceded that a single division at right angles to its fibers, of the external sphincter muscle, will never be attended by incontinence.

An oblique division, however, may allow the ends to widely separate, and should a vicious union take place, the muscle is lengthened, and in this way more or less incontinence follows. So the rule to cut squarely across the muscle should never be forgotten.

When the director, in passing from the external opening of a fistula to the internal, lies obliquely to the muscle, an incision should be made at the external opening so that the director can be adjusted at right angles before division.

Another interesting condition which we have to deal with occasionally is as follows: Two absolutely distinct complete fistulas on opposite sides of the anus. In such a case, would you divide the sphincter in two places? There is considerable risk in a double division. The best procedure is to operate on the larger and deeper fistula first, laying it open in the usual way. The other fistula should be incised and thoroughly laid open, but the sphincter allowed to remain intact. Afterwards, if treated with stimulating solutions of silver, it may heal. If it does not, only a straight simple fistula remains which can be easily incised under infiltration anesthesia after the worst fistula has healed.

Also, when dealing with a large posterior horseshoe fistula when the internal opening is small, it is generally advisable not to lay open the sinus connecting the main tract with the bowel, as it is seldom required to cure the fistula. Of course, all external burrowing should be dealt with in the usual way, but the advantage of not dividing the sphincter is, first, that it may never be necessary, and, secondly, the rest of the wound is not soiled with flatus or feces during the healing process.

When, however, the internal opening is large, there is not much to be gained by leaving this part of the fistula, and as it will eventually have to be laid open, it is best to do it at once.

These remarks, thus far, have presupposed the internal opening of the fistula to be below the level of the internal sphincter muscle.

Fortunately, in the great majority of fistulæ, such is the case. Still, frequently, and often in the cases we least expect it, a high-lying sinus will be discovered at operation. These deeper burrowings almost invariably lie posteriorly to an imaginary line drawn from right to left dividing the anal region into an anterior and posterior half. Judging from a number of cases who had undergone one, two or even three unsuccessful operations at the hands of surgeons of unques-

tioned skill, I am inclined to believe that the proper method of dealing with this sinus is imperfectly understood. In these cases the sinus extends upward outside the muscular walls of the bowel and generally has its termination in the pelvi-rectal space above the levator ani muscle. Now, in order to perfectly drain the pelvi-rectal space, it is not alone necessary to dilate and curette this sinus.

A procedure which I called attention to four years ago in a paper on the treatment of superior pelvi-rectal abscesses, that seems to me of great importance is to incise the fibers of the levator ani a half inch transversely on either side of the sinus. This will maintain better drainage than simply dilating the opening in the so-called pelvic diaphragm. Two small rubber drainage tubes can be inserted and gradually withdrawn as the sinus closes.

The following case is an example of a posterior pelvi-rectal horseshoe fistula dealt with as above described.

A gentleman aged sixty-one was referred to me with what appeared to be an extensive horseshoe fistula of eighteen years' duration.

He had been operated upon eighteen years ago, eleven years ago, seven years ago, respectively, but had never been free from a discharge.

During the past four years several abscesses had been opened, and, taken altogether, he was in a miserable condition and had practically retired from active business.

Examination revealed but one external opening on the right side three inches from the anal orifice over the right tuberosity of the ischium. The internal opening was large and in the usual site, viz., in the middle line dorsally, and between the two sphincters.

The main track could be recognized as extending to the left ischio-rectal fossæ by the cord-like thickening so characteristic of a fistula. At operation, after laying open a typical horseshoe fistula, a sinus was found on the left side which extended upwards for three inches, terminating in a pocket in the superior pelvi-rectal space very close to the rectal wall. In dealing with this high-lying sinus, I did not feel that simply dilating the cavity would maintain free drainage for any considerable time. Dilating a cavity located above the plane of the levator ani in my hands has never proved satisfactory. This procedure simply separates the fibers of this muscle longitudinally, and in a very short time they are so closely coapted that while there may be some drainage, it is altogether inadequate for rapid healing. Therefore, I incised the levator on either side in the manner previously described. Although this was a most extensive fistula, and I had expressed the opinion that three months at least would be necessary for him to get well, the fistula was soundly healed in two months.

In closing, I would like to report a case of fistula in the posterior anal commissure, as it illustrates a class of fistulæ which seemingly present no difficulties, but almost invariably fail to heal satisfactorily, under the usual methods of procedure, as has been pointed out by Brick, of Philadelphia.

Now, the usual incision for such a fistula would be an anteroposterior cut. It will be recalled that posteriorly the external sphincter is attached principally to the coccyx, and as it passes about the anal orifice it forms a Y-shaped arrangement of its fibers. The difficulties often experienced in this class of fistula are that the sinus apparently seems to be doing well at first, but the discharge does not altogether cease and it will be found that a small pocket, more like an ulcer, persists at the ano-rectal line; repeated curettings and applications seem to have little effect upon it. Even the same operation repeated will prove of no avail.

The following case illustrates Brick's method of curing this form of fistula. A man, fifty-eight years of age, had had three unsuccessful operations during a period of eleven years. At operation a blind internal fistula that had its opening posteriorly between the sphincters extended rather deeply, but not above the levator ani, backward for two inches. There was a branching sinus one inch deep just back of the internal sphincter. This fistula was freely incised in the usual way and in addition thereto the muscular fibers of the external sphincter, on either side, were divided for about half an inch near the anal orifice. This procedure put the muscle at rest, and in this way provided for free drainage, and healing was not interfered with by the act of defecation. The wound healed soundly in a very short time, but I feel confident that without the lateral incisions of the sphincter muscle the sinus would have persisted. In fact, a surgeon who was present at the operation stated that he had freely incised the fistula on a previous occasion, and although he had given much attention to the details of the after-treatment, his efforts had proved unsuccessful.

## Clinical Department.

### SALVARSAN ("606") IN THE TREATMENT OF CHRONIC PEMPHIGUS.*

BY RICHARD L. SUTTON, M.D.,
*Associate Professor of Dermatology, University Medical College; Dermatologist to the German Hospital and to the Swedish Hospital, Kansas City, Mo.*

BECAUSE of the great value of salvarsan as a therapeutic agent in syphilis, the probable benefit to be derived from its use in various other chronic disorders, and particularly in skin diseases of doubtful or unknown etiology, has been largely overlooked. Loeb[1] has employed the new remedy successfully in verrucæ vulgares and in lichen planus. Gioseffi[2] has given it a trial in leprosy, but with indifferent results.

In psoriasis and in pemphigus its action, as might be expected from so energetic and power-

* This paper was read, and the patient shown, at a meeting of the Jackson County Medical Society, Jan. 10, 1911.

[1] München. med. Wochenschr., 1910, no. 30, p. 1580.

[2] *Ibid*, no. 49, p. 2526.

ful an arsenical preparation, has been quite encouraging.

Recently I have employed the drug in a case of pemphigus chronicus, and the ensuing benefit was apparently so great, and the improvement in the condition of the patient so startlingly rapid, that the history is worthy of record.

Patient, A. D., farmer, male, single, aged forty-five, referred to me by Dr. W. H. Rees, of Pleasanton, Kan.

*Family history.* — The cutaneous history of the family is negative.

Fig. 1. Showing condition before treatment.

*Personal history.* — The patient is a native of Illinois, and a resident of Linn County, Kansas. He has never had a venereal disease. His general health has always been good.

*Present illness.* — Eighteen months prior to the time of consulting me, an itchy, macular eruption appeared on the chest and upper arms.

In the course of a week, the abdomen and the lower limbs also were involved, and, within a fortnight, large blisters began to appear on the chest and arms. These lesions varied in size from a split pea to the half of a large hickory nut, and developed as bullæ. If the membrane was not ruptured, the enclosed fluid was gradually absorbed, and only a dry crust remained. More often, however, the blisters were torn by accident, in the patient's vain attempts to secure relief from the burning pain by scratching, and, after oozing serum for a few days, the affected areas became crusted over and ultimately healed.

During the year and a half that had elapsed since the onset of the disease, the skin had never been entirely free from bullæ, the number present varying from twenty or more to several hundred.

The lesions had never appeared in definite groups and had not developed in crops, although they were much more plentiful at some times than at others. The mucous membrane of the mouth had never been attacked, and the ocular conjunctiva also had escaped involvement.

Arsenic, in very large doses (forty minims of the liquor potassii arsenitis, three times per day), had proved to be of some benefit, but nothing had ever prevented the development of bullæ, nor given more than temporary relief from the pain.

*Examination.* — The accompanying photograph (Fig. 1) represents the patient's condition fairly well at the time of consultation. Over three hundred vesicles and bullæ were present on the body and limbs. The intervening areas were almost covered with scabs, crusts and the oozing bases of recently ruptured blisters of various sizes.

A lotion containing carbolic acid, zinc oxide, starch, glycerine and lime water was prescribed, and the patient sent to the University Hospital, in this city. A few hours later, 0.6 gm. of salvarsan was injected, subcutaneously, in the interscapular region. No new bullous lesions developed after the first twelve hours, and all subjective symptoms had practically disappeared at the end of two days. The condition of the patient's skin six days after the drug was administered is shown in Fig. 2.

Whether or not the result will be permanent remains to be seen. It may be found advisable to repeat the injection in a short time. At any rate, we have apparently obtained more benefit from the one dose of salvarsan in six days than could be secured by the careful, conscientious employment of the older remedies over a period of many months.

Fig. 2. Showing condition six days after injection of salvarsan.

In my opinion, the result points more clearly to a parasitic factor in the etiology of chronic pemphigus than any other evidence that we now possess.

## Medical Progress.

### REPORT ON GYNECOLOGY.

BY WALTER L. BURRAGE, M.D.

#### ATMOCAUSIS OR STEAMING THE UTERUS.

S. FLATAU, of Nürnberg,[1] sums up the arguments for and against treating the interior of the uterus with live steam, — a method of treatment that has been much used since it was first popularized in Germany ten years ago by L. Pinkus. The author first stated his views at length in Volume 10 of the *Sänger-Martin Monatsschrift*, and now sees little reason for altering the opinions there expressed after a considerable personal experience.

The disinfecting power of steam seems to depend on factors that are difficult to estimate, the temperature, the pressure and the time of application not being the chief features apparently. Vaporization has less effect in a uterus with succulent, hyperemic tissues and a much more destructive action on a uterus the tissues of which are less abundantly supplied with blood and the seat of "fibrosis uteri." Dosage, therefore, is difficult and the danger is encountered of burning the mucosa too deep, whence it has happened that the literature contains a long list of young women suffering with menorrhagia who have been treated with vaporization, with the result that a permanent menopause, with all its attendant discomforts, has been established. Because of this danger the use of vaporization for disinfection and for hemostasis has fallen into disuse except in the treatment of bleeding fibroids, and Flatau uses it only in such cases.

*Vaporization in bleeding fibroids.* — Flatau uses vaporization in those cases of fibroids in which the muscular wall is studded with small tumors either interstitial or subserous, the uterine cavity though enlarged preserving nearly normal proportions. Under no circumstances must vaporization be used if the tumor projects into the uterine cavity and the mucosa has become thinned except when operation is refused or as a palliative measure to combat severe anemia in cases where the improverished blood state contra-indicated operation. In six cases of the last sort that Flatau had treated in the past ten years by vaporization, five were relieved of their flowing and the consequent anemia and they had no other symptoms except amenorrhea. The tumor did not decrease in size in any of these cases. In the sixth case, a woman with a pulse of 120–130 and hemoglobin of 30%, the menses ceased after vaporization, but the tumor increased to twice its former size in the course of five years.

*Sterilization.* — Sterilization by the destruction of the uterine cavity, a method of treatment advocated by Pinkus, the author does not favor, because it induces the premature menopause with its psychic and constitutional disturbances, and the same end is obtained by an operation which is comparatively safe, — resection of the Fallopian tubes.

*Hemorrhages of the menopause.* — In combatting flowing in women who are near the menopause, an exact histological diagnosis must be made from scrapings removed before the vaporization in order not to overlook cancer. The rule is laid down that atmocausis never takes the place of curetting, but supplements it.

Vaporization may cause a sudden elevation of the temperature on the second or third day, but this is generally a lighting up of old inflammatory troubles; therefore, Flatau thinks that atmocausis should not be employed in the presence of diseased tubes and ovaries and old pelvic inflammation. Free drainage of the vaporized uterus should be employed in all cases, and for this purpose a fenestrated glass tube is placed in the uterine cavity at the close of the treatment and left in place for about six days.

*Technic.* — The simplest technic is the best. He uses the boiler described by Pinkus and a cauterizing tube of celluloid on Dührssen's model, providing for a free return of the steam. The depth of the uterus must be taken with the sound before the treatment, and a collar adjusted to the cautery tube so that its inner end may not reach the fundus uteri by 3 cm. because of the danger of perforation of the uterus, an accident which occurred once in the author's experience. The uterine cavity should be dried with gauze strips before the vaporization, which should not last more than twenty to thirty seconds, beginning above and proceeding downwards. Should there be much bleeding from the preliminary curetting, it may be necessary to pack the uterine cavity with gauze to insure its being dry before the vaporization is begun.

Flatau concludes that atmocausis is applicable to only a limited number of cases of uterine hemorrhage.

#### RUT, OVULATION AND MENSTRUATION.

M. Pottet[2] summarizes the thirteen communications of Regaud and Dubreuil to the Société de Biologie during the years 1907–1909 on the subject of rut, ovulation and menstruation.

*Rut.* — It has been generally believed that rut, the periodical sexual heat of animals, and menstruation, its representative in women, are dependent on the internal secretion of the corpus luteum of the ovary (Fraenkel-Villeminn), but Regaud and Dubreuil point out that this theory does not apply to the rabbit. Their observations show that a female rabbit only accepts the male during the rutting period, and this is the only sure sign that rut is present. Under these conditions the rabbit becomes pregnant nine times out of ten, the rupture of the follicles taking place from seven to ten hours after coitus, and a corpus luteum being formed in the empty follicle whether the ovule has been fecundated or not. The rut seems to be determined by the existence of follicles almost ready to burst, the coitus actually causing their rupture.

If the theory of Fraenkel-Villeminn were true for the rabbit, there should be found in the ovaries soon after coitus, rut being present, well-formed

corpora lutea formed in follicles which had ruptured before coitus, but when the ovaries are examined previous to seven hours after coitus, the follicles are found to be intact. Therefore, the presence of the corpus luteum does not coincide with rut, and the sexual desire can have nothing to do with a secretion from the corpus luteum.

The authors investigated the influence of the interstitial gland of the ovary in rabbits in producing rut and came to the conclusion that the appearances of the gland vary so much in different rabbits and in rabbits of varying ages that definite statements are difficult to make. In 16 rabbits examined just after the period of rut, the interstitial gland was well developed in 5 cases and poorly developed in 11 cases; therefore, they conclude that the interstitial gland of the ovary has no direct influence on rut.

Lataste showed by his researches that sexual phenomena were rhythmic in the females of several species of rodents, the rhythm being thirty days.

Regaud and Dubreuil adopt this view and show further a new point, namely, that the rut is influenced by the presence of the male, first, because female rabbits living entirely separated from the male have rut at very irregular intervals; second, when living with a male, unless pregnant, they are, in the majority of cases, covered every thirty days, causing the suspicion that copulation has an accelerating influence on rut.

*Ovulation.* — In answer to the question, Is ovulation spontaneous, the view generally held to be true among the females of mammalia, they hold that probably it is not, (1) because if a female rabbit has coitus during the rutting time several hours elapse before the rupture of the follicles in the ovary, and then a rupture occurs in the great majority of cases; (2) if coitus is prevented, follicles are rarely found ruptured, even after several days of rut.

Regaud and Dubreuil deny the statement of Villeminn that the follicles rupture in female rabbits who are separated from the male. In nine rabbits isolated in this way for six to seven weeks they were unable to find a trace of spontaneous ovulation upon examination of the ovaries. The authors think that ovulation is consecutive to rut and to coitus in other mammalia besides the rabbit, but in women it is certain that ovulation is spontaneous in a great number of cases; the influence of sexual excitement is probable, but remains to be proved.

*Menstruation.* — Ancel and Villeminn have adopted Fraenkel's theory that menstruation is caused by the activity of the corpus luteum. According to them, the Graafian vesicle bursts not at the time of the menses nor immediately before or after, but twelve or fourteen days before the onset of menstruation. The corpus luteum formed after the bursting of the follicle reaches its maximum of development two to four days before the menses begin; therefore, it is logical to admit that it is the internal secretion of this body that causes the flow. Moreover, corpora lutea are found in the ovaries only between puberty and the menopause. To this Regaud and Dubreuil reply that the Graafian follicles ripen and burst only between puberty and the menopause, and one might conclude, therefore, that the ripening of the follicles is the cause of menstruation, being careful to avoid the "*post hoc, ergo propter hoc*" argument. The chronology of ovulation and menstruation is notably inconstant, and to disprove Fraenkel's theory they cite the case reported by Mandl, in which a young girl, always regular in her menstruation, was operated upon the day before her expected catamenia. Premenstrual changes were found in the uterine mucosa and a large follicle in the ovary ready to burst, but no trace of a corpus luteum.

The structure of the corpus luteum does not vary much in different animals, and, therefore, if it is the cause of rut or menstruation in one animal, it ought to be in all. The conclusion is reached that the hypothesis that the corpora lutea are the glands of internal secretion is histologically probable. But these organs are not the the cause of rut in animals and very probably are not the cause of menstruation in woman. The subject is still open to investigation.

[It is to be noted that Fraenkel last September announced at the International Congress at St. Petersburg the results of further experimental research on this subject,[3,4] in which he thinks he confirms his previous theory and demonstrates that the corpus luteum has an internal secretion, is responsible for the rhythmical engorgement of the uterine organs preceding menstruation, and the changes in the endometrium which are essential for the embedding of the ovum. From observations at operations on the ovaries, he shows that the follicle ruptures about nineteen days after the beginning of the last menstruation; that about eight days later the corpus has reached its full development; that it begins to involute at the beginning of the next menstruation and that by the end of the menstruation it has disappeared entirely.]

### CARCINOMA OF THE CERVIX DEVELOPING AFTER SUPRAVAGINAL HYSTERECTOMY.

G. Uhl[5] reports a case of carcinoma of the stump of the cervix that had become inoperable when seen, developing after the removal of the body of the uterus and the ovaries ten years before for cancer of the ovaries. F. Weisse[6] adds another case. In this a patient of forty-five was operated upon in June, 1905, for multiple fibroids by the usual amputation of the uterus, leaving the cervix *in situ*, making a good recovery. In July, 1910, she presented herself with advanced cancer of the cervix, which was removed by a radical abdominal operation, with dissection of the parametrium and the lymph glands of the pelvis.

H. Hintertoisser[7] reported two cases and called attention to the association of fibroma and carcinoma in the same tumor, insisting on the importance of having the removed fibroid tumor examined microscopically during the operation,

so that should cancer elements be found in the cervical portion, the entire cervix uteri may be removed. This point has been emphasized by T. S. Cullen, of Baltimore.[8] This author[9] has observed carcinoma of the cervix associated with fibroids in 18 cases among the 1,674 cases of myomata examined by him.

C. Fleischmann[10] summarizes the cases of cancer developing in the stump of the amputated uterus reported in the literature, quoting Winter as giving the following undoubted cases in 1906: Schenk, 1; Jacobs, 2; Savor, 2; v. Erlach, 1; Freund, Jr., 1; Olshausen, 1; Tetzong, 1; Chrobak, 2; Kauffman, 1; Fleischmann, 1; Noble, 1; Quénu, 1; Richelot, 3. Olshausen (1907) added Pawlik, 1; Von Rosthorn, 1; Lumpe, 1. These added to the cases of Hintertoisser, Uhl and Weisse make a total of 25 authentic reported cases, without making any exhaustive search of the literature. Winter mentions additional cases as follows: Richelot, 1 (Mériel[11] says that in 1905 Richelot reported 6 cases); Von Hartmann, 1; Le Dentu, 2; Ch. Martin, 7, and Norris, "several cases." Therefore, we must conclude that these cases are of reasonably common occurrence, for only a portion of them, necessarily, appear in print.

### THE RELATION BETWEEN FIBROIDS AND CONCEPTION.

The subject of myomata in pregnancy, labor and the puerperium was discussed by Schauta, Engström and other noted German gynecologist, at the International Congress at Budapest in August and September, 1909. Since that time there have appeared in the literature several important articles bearing both on the relation of fibroids to fertility and on the general topic of fibroids complicating pregnancy and labor. For instance, A. Martin[12] says: The older authors held to the view that myomata hindered pregnancy, and in adding together the large number of reported cases of married women with fibroids who were sterile, as Olshausen did in Veit's Handbuch, the total is 1,504 women, of whom 482 were sterile, a percentage of 31. On the other hand, P. Muller, from the analysis of a large number, made the percentage of sterility 8–10. At the present time the frequent occurrence of myoma complicating pregnancy proves that the two conditions coexist more often than was thought when the opportunities for exact observation were less often afforded. We observe young women with rapidly growing tumors, and we see those suffering with flowing, pain and all the discomforts caused by fibroid tumors, still becoming pregnant, and the conclusion is justified that neither the situation, the size, the singleness or the multiplicity of the tumor can prevent conception. It is possible, as Hoffmeier has alleged, that myoma even increases the capability of conception by its stimulating effect on ovulation and menstruation. O. Goetze[13] has an exhaustive article on the relation between this bland tumor of the uterus and conception, making use of the material in the clinic at Greifswald for the two years from Nov. 1, 1907, to Nov. 1, 1909, as the basis for his conclusions.

First he analyzes his statistics for the purpose of throwing light on the question as to the frequency of fibroids. Among 1,500 women in the gynecological clinic, 122 had fibroids, or 8.1%. The percentage in the clinic at Tübingen is quoted as 10. In the following clinics both private and hospital patients are included; Hofmeier, 4.3%; Essen-Möller, 4.7%; Kleinwächter, 4.4%. Autopsy statistics gathered by Essen-Möller showed a presence of fibroids in 12.6% of all the bodies of women that came to autopsy, and Winkel had a percentage of 12.7 in similar circumstances. It would appear that fibroids are more often encountered among the private patients than in the hospital clinics, for Hofmeier had 9.7% in his private patients and only 4.1% among the patients in his public clinics, and Goetze, among 370 private patients, had 79, or 11.6%, while in the hospital clinic of 1,130 women, there were 43, or 7%, having fibroids. Most of his cases were between the ages of forty and fifty, the usual age when patients with fibroids apply for treatment.

Of the 122 women with fibroids, 105 were married and they were of the average age of 44.5 years. Of these, 22, or 21%, were sterile. This is to be compared with the figures of Hofmeier, 26.8; Löfquist, 33; Fraenkel, 26.5; Scipiades, 33.5, and the combined statistics of Olshausen, already referred to, 31%. In comparison, the author puts forward the facts gathered from 730 women attending the gynecological clinic who were between the ages of thirty and seventy years. In them the percentage of sterility was 6.95. Hofmeier found the percentage of sterility in all the married women of his gynecological clinics to be 11. Therefore, the author concludes that the presence of fibroids raises materially the percentage of sterility and that a definite though not exactly definable causation exists between myoma and sterility.

As to the number of children borne by the 105 women who were affected by fibroids, there were 327, or 3.1 per patient. The 730 married women of the clinic showed a fertility in number of children of 4.4 per patient, corresponding exactly with the number of children to a marriage as given in the Imperial Bureau of Statistics for Prussia.

The author concludes that small subserous myomata are no bar to fertility, and even large subserous ones do not prevent conception. The submucous tumors form the greatest hindrance to conception, and the more so the greater the changes in the endometrium and the greater the amount of flowing. The interstitial growths hold a middle place, while rare tumors of the cervix are less an obstruction to conception than the tumors of the body of the uterus. Should pregnancy occur, the myoma increases the danger of abortion.

T. Landau[14] contributes a most interesting monograph of one hundred and sixty-two pages and seventeen large and beautifully executed

plates in the elucidation of this subject. The same author published a treatise on the treatment of pregnancy and labor complicated by myoma in 1891, in which he formulated the principles of the pathology and treatment of this condition that are now, nearly twenty years later, generally accepted by the profession. The wealth of material at the command of the brothers Landau has afforded them exceptional opportunity, probably the best in Europe, for the study of myomata complicated by pregnancy and for the development of a good surgical technic in the treatment of fibroids. The development of the operative technic has shown great advances during the past twenty years. In 1885 Gusserow had a mortality of 122 among 395 operations on myomata, or 33.9%. In 1897 Olshausen, 45 deaths in 806 operations, or 5.6%, and the combined statistics of Winter in the year 1904 gave for 689 operations, 32 deaths, or 4.6%. Landau now reports 283 conservative and radical abdominal operations on myomatous uteri that he and his brother have performed in the last five years, the patients having all sorts of complications, with a mortality of 2 cases. [This is comparable to the results obtained by Kelly and Cullen in the Johns Hopkins Hospital.[5] In three years and a half up to Jan. 1, 1909, they reported 230 abdominal myomectomies or hysteromyomectomies, with 2 deaths.]

In this review we shall concern ourselves only with the first chapter of Landau's monograph, that on myoma and fertility. The remaining two chapters, on the relation between myoma and pregnancy, labor and the puerperium, and the surgical treatment of fibroids, are outside the scope of this article.

Landau considers that myomatosis uteri, contrary to the views formerly held, is often a disease of early sexual life, citing an article of his brother published in 1908, in which attention is called to the fact that among 400 of their fibroid cases operated upon for severe symptoms, 42 women were between the ages of twenty and thirty years.

As long as there is a passage for the spermatozoa to reach the ovum and a small portion of endometrium available for the embedding of the ovum, pregnancy may occur. The obstacles to conception are flowing and profuse leucorrhea and inflammatory affections of the pelvic organs, which may be enumerated as: (1) Active and passive hyperemia which attend the formation of myomata. (2) Infection. (3) The mechanical exfoliation of the surface epithelium of the tumor and thus the formation of adhesions. (4) Accumulation of blood in the tubes or the formation of hematosalpinx from the pressure of a myoma on the tube. The size, the situation or the number of the tumors which deform the uterus do not much matter so long as there is a way for the spermatozoa and the ovum.

Landau is not surprised to find on investigating the histories of their last 250 cases that 182 had been pregnant and 68 sterile. An analysis of the 68 showed that only 15 had marked disease of the adnexa, and in these there were perimetritis, perisalpingitis or perioöphoritis of very mild grade in 13, and the author is in doubt whether these inflammatory processes are the result of myomatosis or have developed in later years in women in whom pregnancy was barely possible or improbable; therefore, inflammatory processes in the pelvis in myoma are not to be considered seriously as causes of sterility. Inspection of the tabulated cases shows that among the 68 sterile women, myoma was the only pathological condition found in 40, and that in the remaining 28 some other factor must be sought as the possible cause of the sterility, and the mere fact that of the women upon whom operation was necessitated because of the presence of a fibroid, three fourths had been pregnant, proves that the alleged tendency of the myoma to cause sterility can exist in only a small proportion of the cases. Furthermore, it appears from the data in the author's tables that the fertile myomatous women who underwent operation exhibited changes in the adexa similar and to the same extent as those found in the unfertile, so that the presence of myomata in the uterus has no effect whatever upon conception. In refutation of the opinion that myoma disposes toward sterility, the author gives his observations in his 250 cases. Eighty-four of these had had more than 2 children, nine had 5 children, six had 6, three had 7, four had 8, one had 10 and one 13, by normal labors.

He does not think much weight ought to be attached to the combined statistics of different authors or the variations in private practice, in public clinics, or in different countries, for the same data are not secured in every case.

To the question whether fibroids may not occasionally in a certain proportion of cases diminish the capability of conception, the author answers that as it is impossible to get all of the facts as to the anatomical and mechanical relations of any particular tumor, the question is too broad to be considered. All myomata are intramural or interstitial in the beginning and become submucous or subserous by the contraction of the uterine muscle fibers; the tumors move about in the course of time and, therefore, a myoma may cause obstruction of the uterine cavity or the Fallopian tube at one time, and, by its gradual migration, the obstruction may be removed later, or the reverse may prove true.

Notwithstanding the definite statement of the percentage of sterility in fibroids in general, no definite prognosis can be formed for the individual case because daily observation shows women who, according to theoretical considerations and the general principles laid down, should be incapable of conception, nevertheless they are pregnant. Therefore, Landau is of the opinion that myomatous women should be advised to marry.

# Reports of Societies.

## NORTH CENTRAL SECTION OF THE AMERICAN UROLOGICAL ASSOCIATION.

MEETING HELD AT THE GREAT NORTHERN HOTEL, CHICAGO, JAN. 5, 1911.

THE President, DR. R. H. HERBST, of the Chicago Urological Society, in the chair.

### POSITION DRAINAGE IN SUPRAPUBIC PROSTATECTOMY.

DR. HENRY J. SCHERCK, St. Louis, Mo.: To my mind the question of drainage has always been the main objection to the performance of the suprapubic method. The inspiration for the abdominal position after suprapubic prostatectomy came to me by observing a colleague perform the Gilliam operation in which the position described was utilized. All drainage of suprapubic bladder wounds depends either upon syphonage or suction. My observation covers five cases recently operated upon by the suprapubic method. The principal objection to the ordinary form of drainage, either syphon or suction, is that it does not completely empty the bladder of decomposed or septic urine, and allows it to become absorbed in a freshly wounded bladder and space of Retzius. The abdominal position does not allow the septic material to remain in contact with these surfaces, and this minimizes the chances of absorption.

#### DISCUSSION.

DR. L. W. BREMMERMAN, Chicago, demonstrated an apparatus which consists of an arrangement by which he can drain the bladder suprapubically or perineally, as the case may be, by automatic interrupted siphonage. During the first twenty-four hours following suprapubic prostatectomy the bladder can be emptied every five minutes, keeping it dry and keeping the dressing on the abdomen practically dry and making the patient comfortable.

DR. GUSTAV KOLISCHER, Chicago: I firmly believe that position has nothing to do with the development of post-operative pneumonia, and the only way to prevent this condition is by proper breathing exercises, with the patient lying on the back or sitting up. The position described by the essayist was used in various conditions years ago, as, for instance, in cases of peritonitis, and in spite of it, many patients developed hypostatic pneumonia. What are the dangers following suprapubic prostatectomy or any suprapubic operation? One is post-operative hemorrhage, and the other is infection around the bladder.

DR. E. G. MARK, Kansas City, Mo.: The first thing we have to look after following suprapubic operation of any kind is hemorrhage; second, infection or infiltration into the abdominal wall or perivesical tissues, and, third, hypostatic pneumonia. I cannot agree with Dr. Kolischer that position makes no difference in regard to lung cases, because I have had the misfortune within the last week to lose my first case of suprapubic work from hypostatic pneumonia. It was a case in which gas anesthesia was used, and I am convinced that in this case position had a great deal to do with the development of the pneumonia.

DR. RUTHERFORD B. F. GRADWOHL, St. Louis, Mo.: I think the method of drainage described by Dr. Scherck is admirable in respect to the prevention of hypostatic pneumonia.

DR. ARTHUR DEAN BEVAN, Chicago: Suprapubic drainage is very much better carried out in a simple and effective way either after an exploratory bladder operation, a suprapubic stone operation or a suprapubic prostatectomy. I am employing this simple method: I take a tube about the size of the index finger, measuring it accurately, so that it will project three quarters of an inch into the bladder; then I take a fine catgut suture and introduce it into the suprapubic wound, stitching both above and below the tube. It almost invariably requires but a single suture above and a single suture below the tube. This suture passes through, first, the bladder wall, and, second, takes a good bite of the tube and goes through the opposite wall, and is then tied in the space between the bladder and symphysis where we tuck in a small cigarette drain with iodoform gauze, projecting beyond the gutta percha.

DR. SCHERCK (closing): The main objection to suction is the minute air gets into the tube the suction does not work. The tube that is introduced into the bladder wound must be short. I agree with Dr. Bevan except with the addition, that I put the patient on the belly to facilitate drainage.

### GENITAL TUBERCULOSIS.

DR. F. W. ROBBINS, Detroit, Mich., reported twenty cases of genital tuberculosis, and in only two of them was there a possibility of tracing the relationship between the condition diagnosed tubercular epididymitis and a previous gonorrhea. In neither of these patients was the tubercle bacillus found, and the diagnosis of tuberculosis may well be questioned, although he was very suspicious in both instances. The twenty cases were then related in detail.

The author shows that rarely does genital tuberculosis follow venereal disease; that about 60% of cases of genital tuberculosis are a part of the general tubercular infection; that occasionally the disease may be so located in the external genitals as to make radical operation wise, but more often the disease of the external organ is associated with that of the prostate and vesicals, even when the bladder and kidneys are healthy; that in view of the effect of guaiacol in relieving urinary irritation, and of tuberculin and proper hygienic conditions, in increasing the resistance of the individual, it is seldom good practice to do the extensive operation recently so brilliantly described by Dr. George Whiteside.

#### DISCUSSION.

DR. HUGH CABOT, Boston: In regard to genital tuberculosis, my conclusion has been practically the same as that of Dr. Robbins. I have seen several cases in which tubercular epididymitis occurred in patients who had had gonorrhea, but many people have acquired gonorrhea accidentally. I have never seen a case in which it occurred in such a way as to suggest to me that gonorrhea was the cause of the subsequent tuberculosis, even to the extent of lowering vitality. In regard to age, I was surprised this year to see a case of double epididymitis in a child one and a half years old. I was doubtful about the diagnosis. I was moved to explore, and a diagnosis was made by the microscope. Both epididymes were involved. The vas was not implicated on either side, and there was no involvement of the vesicals or prostate.

Dr. Daniel N. Eisendrath, Chicago: My experience is somewhat different from that of Drs. Robbins and Cabot. In two cases I distinctly recall there was a direct relation between gonorrhea and tuberculosis. There were two factors which influenced the clinical picture. First, in both cases a preceding gonorrhea had seemingly furnished the ground for the localization of the tubercle bacillus; second, it looked in both cases as though the tuberculosis came on top of the gonorrhea, which took a more acute course than it would as we ordinarily see it. One case, treated for two months, had a greenish typical discharge containing gonococci, and this was accompanied by enlargement of both epididymes. In one case the thing that attracted attention was an abscess which ruptured through the scrotum. We examined the pus for gonococci and found them, and did not suspect at first there was tuberculosis. The whole process lasted, before I saw the patient, two months. I advised antigonorrheal treatment, and this was continued for another two months without benefit. We examined the pus discharge for tubercle bacilli, suspecting that the cause was not purely one of gonorrhea, and found a large number of them. We followed this case to autopsy. The whole course lasted about a year, at the end of which time the patient died from uremia, and autopsy showed extensive tuberculosis, a mixed infection not only low down where we had removed the epididymis, but mixed infection of the kidneys, also showing gonococci, tubercle bacilli in the kidneys, pus and a stone in the kidney.

Dr. R. H. Herbst, Chicago: A man came to the clinic at Rush Medical College in January of last year with a large nodule in the upper pole of the epididymis, the size of an English walnut, in the region of the external ring, and painful. There were two nodules in the prostate, and he had frequency of urination. He was put on tuberculin, and has been treated off and on with it ever since, and at the time I presented the patient to the Chicago Urological Society his cord was clinically free, the nodule at the external ring had disappeared, and the nodules in the prostate had likewise disappeared, as well as the frequency of urination, one week after treatment. He still has a small nodule in the upper pole of the epididymis as large as a hazelnut. We suggested that this nodule be removed, but he refused to have it done. We have kept on with tuberculin since, and the result has been good. I think tuberculin, if used in the treatment of these cases properly, is valuable, and should be used in almost every case, because our results with surgical interference have not been as good as they have with this form of treatment, plus hygienic treatment.

Dr. G. Frank Lydston, Chicago: I recognize it is not an easy matter to prove the association between gonorrheal infection and septic tuberculosis, and we have to fall back on the rules of logic. A large majority of cases of genital tuberculosis we meet in the city have been preceded by gonorrhea. Patients have been infected at one time or another with gonorrhea, and they come to us with the belief that the tubercular trouble is more or less of gonorrheal origin. If it is true that gonorrheal infection, as it is true of all other infections, reduces resistance and does not predispose to tuberculosis, then we have a rule that differs from all other rules with reference to tuberculosis. An individual with a lowering of the power of resistance in the mucosa, other things being equal, is particularly susceptible to infection by the tubercle bacillus. The chief argument against the relation of gonorrhea to tuberculosis of the urogenital tract was missed altogether by the opponent of that theory, and that is that infection, as a rule, is descending, coming from the kidney, and from the substance of the kidney, rather than from the pelvis, excepting secondarily. Gonorrheal infection of the kidney is relatively exceptional, as contrasted with the sum total of cases of gonorrhea.

### DIFFICULTIES AND LIMITATIONS OF DIAGNOSIS IN ADVANCED CASES OF RENAL TUBERCULOSIS.

Dr. Hugh Cabot, Boston, read a paper on this subject.

### DISCUSSION.

Dr. Arthur Dean Bevan, Chicago: I am accustomed to divide these cases into three groups, namely, those which are distinctly genital tuberculosis; those which are distinctly urinary tuberculosis, and the difficult cases that are on the border line, where it is difficult for us to determine, in the first place, whether the origin is genital or urinary, and to determine at the time of the examination the extent of involvement, whether it is limited to one or two kidneys, whether the kidneys and ureters are involved, or whether the kidney, the bladder, the prostate and epididymis are implicated. It has been shown that these cases of genito-urinary tuberculosis originate in one of three positions, either in the epididymis, the prostate or kidney. In cases of genital tuberculosis, if we are quite certain there is a definite gross focus which overshadows everything else in the case, as, for instance, the epididymis and vas, it should be removed. On the other hand, I am quite certain that general hygienic treatment is quite as valuable, if not more so, than surgical intervention. In the classical, typical case, where modern methods of diagnosis will enable us by cystoscopic examination and catheterization of the two kidneys to obtain the urine separately from each kidney, where we can at once definitely locate the lesion in one kidney, modern surgery demands nephrectomy.

Dr. Rutherford B. F. Gradwohl, St. Louis, Mo.: I would make a plea for continued unremitting efforts with the catheterizing cystoscope to make an early diagnosis in this condition. A recent case, in which I was associated with Dr. Bransford Lewis, illustrated that. The patient had a history of frequent micturition for a year and a half. He had been under the observation of two practitioners for several months, who made every effort to make a diagnosis except by the aid of the catheterizing cystoscope. They examined the urine repeatedly, but were not able to come to a conclusion as to whether the case was tuberculous or not. Finally, by catheterizing the ureters, Dr. Lewis found urine from the right side cloudy with pus, and the left side was clear. Tubercle bacilli were demonstrated by animal tests in the right kidney, and a large ulcerated kidney was removed. From the standpoint of my experience in bacteriological and laboratory investigations of these cases, the quantity of tubercle bacilli thrown off in these cases has no relationship to the extent of the lesion, which may account, in a measure, for the difficulties in diagnosis.

Dr. Gustav Kolischer, Chicago: Catheterization of the ureters and observation of the ureteral openings through the examining cystoscope should be done in doubtful or difficult cases only after tuberculin has been injected. As to functional tests of the kidney, Dr. Louis Schmidt and I have pointed out that they are absolutely unreliable in a positive and negative sense, as we cannot prove by these tests that a kidney is insufficient. This was proven in two cases which Dr. Schmidt and I examined together.

Dr. Daniel N. Eisendrath, Chicago: A patient was sent to me with a diagnosis of suspected tuberculosis of the kidney on account of tubercle bacilli

having been found in the urine, the bladder being negative. This patient had a series of chills, fever and sweats, which came on at irregular intervals, simulating an ordinary colon bacillus pyelonephritis. The clinical picture was such that for a long time we doubted the diagnosis of tuberculosis, in view of the fact that repeated examinations, after a positive single finding of tubercle bacilli, showed no tubercle bacilli. Cystoscopic examination was negative, but ureteral catheterization showed pus coming from one kidney. We exposed this kidney. I incised the capsule. I saw no evidences of tuberculosis on the surface of the kidney, and the blood flowing from the cut in the capsule so obscured our view for a few seconds that it was impossible to tell whether or not there was any tuberculosis present. Having taken the precaution to put hemostats on the pedicle of the kidney, the clots were wiped off, and then exploration showed that there were a number of caseous foci low down close to the lower pole that we had not seen on account of the fact that the clots of blood obscured them. This case emphasised the necessity of hemostasis when there is an exploratory operation done and foci are not evident.

The paper was also discussed by DR. E. G. MARK, Kansas City, and in closing by DR. CABOT.

DR. WILLIAM N. SENN, Chicago, exhibited and demonstrated an operation cystoscope of his design.

### TREATMENT OF SYPHILIS WITH "606."

DR. CARL WAGNER, Chicago, has come to the following conclusions, after a personal visit to Ehrlich at Frankfort, Schreiber at Magdeburg, Weintraub at Wiesbaden, and Gennerich at Kiel: "606" is most actively and painlessly applied as an intravenous injection by the aid of the Cassel syringe. The duration of the treatment should not be less than six minutes. The advantages over mercury are: (1) People who, for some reason or other, will not submit to inunction or to any protracted treatment, are more apt to try a single injection of "606," and, if the infection is primary, may be cured permanently. (2) In doubtful cases, where a primary lesion has not yet developed, but the patient has been exposed to syphilitic infection, "606" may be considered. One single dose may act as a preventive. (3) In primary cases, especially if excision of the initial lesion can be combined with a full dose of "606," it might prove abortive, if used early, because the spirochetæ are not blood parasites, but pass only once through the blood current, and quickly nestle in the tissues. (4) Most cases, which do not respond to mercury any more, and cases of real malignant syphilis, have certainly found in "606" their true friend, because with "606" spirochetæ do not exist, according to the more careful observers. (5) With "606" we cure, without any risk, the fetus in utero and the newborn through lactation of the injected mother, which must be considered as one of the most wonderful properties of "606." (6) "606" has a special elective effect upon diseased tissue, as observed in the good results obtained in psoriasis, lichen simplex verrucæ and so on. (7) We must mention the strong tendency to epidermization, even in the most obstinate and inveterate cases. If we further consider the disposition of the spirochetæ in regard to where they settle in the lymphatic spaces and tissues, and where they surround themselves with a wall of connective tissue, then any means which can cause the spirochetæ to break through this wall and effect a flow of lymph through this depot again must be considered a great aid in wiping out such syphilitic deposits, as then "606" can reach them. Such exists in fibrolysin, which, therefore, might be combined with the general treatment.

### DISCUSSION.

DR. R. H. HERBST, Chicago: My experience with this remedy has been limited to cases of early syphilis, and to the use of the remedy in neutral suspension by either subcutaneous or intramuscular injection. My cases were all Wassermann positive previous to injection, and all showed spirochetæ in smears. The Wassermann reaction following the injection became negative as early as the sixteenth day in one case, and as late as the eighth week in another. Others varied between these periods. The syphilis was probably more marked in the mucous membrane lesions, such as mucous patches, anal ulcerations, intra-urethral ulcerations and so on. The skin manifestations, indurations, adenopathies, etc., did not disappear any more rapidly than with good mercurial treatment. In fully 80% of my cases I have seen recurrence at the present time. These recurrences have taken place as early as three weeks after the injection. The dosage varied from 4½ dcgm. to 6 dcgm.; some were injected subcutaneously, while most of them were injected intramuscularly.

DR. LOUIS E. SCHMIDT, Chicago: I have had experience in treating twelve cases with "606," and of that number there was one that I considered cured. In this case the symptoms and signs disappeared following the first injection, three months ago.

DR. HENRY J. SCHERCK, St. Louis, Mo.: Our experience in St. Louis has been limited to sixteen cases. The cases were selected on account of the virulency of the infection and the stubbornness of the lesions. Very careful examinations were made, and Wassermann tests were made before and after injection. Dr. Engman, who is a careful observer, reported his findings recently, two or more months having elapsed since these patients were injected. Our impression is that recurrences are the rule after the use of salvarsan. In only two or three cases, at the outside, has the result been phenomenal, and in one of these, unfortunately in the last few days, evidences of recurrence have manifested themselves. In one case of a man with a large gumma of the calf of either leg and forearm, the result was phenomenal. The whole business cleaned up in the course of two or three weeks. This is one case in which there has been no return, but in the majority of cases there has been a recurrence.

### A CASE OF AIR EMBOLUS OCCURRING DURING OPERATION UNDER AIR-INFLATION URETHROSCOPY.

DR. ERNEST G. MARK, of Kansas City, Mo.: In the use of air-inflation urethroscopy for work in the urethra within the past year I have observed certain localized emphysematous symptoms to arise and believe, therefore, that certain dangers may ensue therefrom. Fenwick, in urethroscoping under air inflation a case of stricture complicated by a recent false passage, noted an emphysematous condition to arise and speculated on the possibility of certain associated conditions due to the unfiltered air passing into the tissues. The case which forms the basis of this paper was that of a patient in whose urethra there was present a small band-like stricture on the floor of the urethra just anterior to the penoscrotal junction. In operating upon this patient under air inflation, after division of the stricture there was a localized emphysematous condition in the neighborhood of the stricture and almost immediately the patient complained of pains in the epigastrium and began to cough. He became rapidly cyanotic and the radial pulse became imperceptible. Auscultation over the cardiac area revealed the "whirr" of what was apparently considerable quantities of air passing through the heart. The heart sounds apparently ceased and respiration

progressively ceased as in the dying. The pupils were fully dilated and the eyes were fixed; the lower jaw was dropped. In fact, the whole appearance was that of a cadaver. Under artificial respiration and the hypodermic use of whiskey the patient began to slowly recover consciousness. The feeling of depression in the epigastrium was still complained of and this condition lasted for about a week. Local emphysema was not greatly marked and seemed to involve only the cellular tissue of the pendulous urethra. There was no emphysema of the scrotal tissues. The following day the patient complained of tenderness in the hypogastrium, especially marked on the left. Examination revealed a fairly extensive emphysema of the abdominal wall which slowly disappeared in about one week. I believe there can be no question but that the causative factor of the serious symptoms in this case was air embolus. The amount of air which was forced into the circulation without a fatal issue is, however, astonishing.

LOCAL PARESIS OF THE URINARY BLADDER.

Dr. Gustav Kolischer and Dr. Harry Kraus, Chicago, contributed a joint paper on this subject. There are certain cases of paresis of the bladder that are caused by edema of the bladder wall. This edema may be produced by gross mechanical interference with the circulation by the impaction of tumors, whether they are a pregnant uterus, or any other uterine tumor, or an ovarian tumor. Or this edema is the consequence of inflammatory changes in the adjacent organs. That the bladder is paretic is shown by the fact that catheterization alone does not lead to a satisfactory emptying of the bladder, but that outside pressure has to be resorted to in order to express all the urine. That the edema of the detrusor is the cause of the vesical paresis is proven (1) by the cystoscopic findings; (2) by the palpatory findings after the bladder was drained; (3) that there are no disturbances of the central nervous system to be found; (4) that this bladder paresis disappears without any special treatment after the factors that interfere with the circulation are removed, whether they have been purely mechanical or of inflammatory character.

THE CAPUT EPIDIDYMIS AN EXCRETORY ORGAN.

Dr. William T. Belfield, Chicago: The head of the epididymis is a part of the middle kidney, which functions as a kidney in frogs and fishes, but is superseded in man by the permanent kidney. The efferent tubules constituting the head of the epididymis are the convoluted tubules of this early kidney. That they are secretory organs is indicated by the motion exhibited on traversing these tubules by the previously motionless spermatozoa. Their excretory function is indicated by the infection of these tubules with various organisms derived from the blood, e. g., those of tuberculosis, syphilis, typhoid fever and colon bacilli. These infections may extend along the genital tract to the prostatic urethra. Until recently, all infections of the kidney were assumed to ascend from the bladder. It is now known that many infections of the bladder descend from the kidney. Similarly we have been accustomed to regard all infections of the genital duct as ascending from the deep urethra; but must realise that in certain cases these infections begin in the convoluted tubules (head) of the epididymis and descend to the vesicles and deep urethra, there being a complete analogy between the second kidney (caput epididymis) and its duct on the one hand, and the third (permanent) kidney and its duct on the other. Hence to limit treatment of all genital duct infections to the prostate and vesicles is as irrational as to limit treatment of all urinary infections to the bladder.

## Book Reviews.

*The Essentials of Histology*, Descriptive and Practical, for the Use of Students. By E. A. Schäfer, M.D., Sc.D., LL.D., F.R.S., Professor of Physiology in the University of Edinburgh. Eighth edition. Philadelphia and New York: Lea & Febiger. 1910.

This book, now in its eighth edition, is firmly established in popular favor as a concise, well-arranged and admirably illustrated treatise on the microscopic anatomy of body tissues. It is essentially a textbook, and as in previous editions is arranged in lessons, fifty in number, each lesson being preceded by instructions to the student regarding the making of preparations and the particular objects to be studied. In spite of certain additions, especially of illustrations, the volume is of convenient size and weight, printed on somewhat thin paper, on which the cuts are excellently reproduced. It is an unusually good piece of book-making.

*Studies in Invalid Occupation.* A Manual for Nurses and Attendants. By Susan E. Tracy. Boston: Whitcomb & Barrows. 1910.

This volume, the product of a series of practical studies in the classes of the Training School for Nurses of the Adams Nervine Asylum, Jamaica Plain, Mass., presents interesting suggestions in guiding the occupations of "typical invalids," who are appropriately described under such captions as "the child of poverty, the child of wealth, the orthopedic patient, the patient in quarantine, the one-handed, the impatient boy, the grandmother, the business man, the pregnant woman, the blind and the insane." Occupation is the balance-wheel of life, and to provide it for those who are temporarily or permanently deprived of opportunity for normal human activity is one of the important and often most difficult duties of the nurse. To provide it wisely may mean the saving of life by making it tolerable. The present book seems a valuable aid to this desirable end. It is well written and illustrated, and has an admirable introduction by Dr. Daniel H. Fuller. The author deserves great credit for her work, which should be of help and use to all who have the care of invalids.

*Medical Electricity and Röntgen Rays*, with Chapters on Phototherapy and Radium. By Sinclair Tousey, A.M., M.D., Consulting Surgeon to St. Bartholomew's Clinic, New York. Philadelphia and London: W. B. Saunders Company.

As a first impression of this work, the reader is convinced that nothing has been omitted which can properly be embraced under its title. That portion dealing with the subject of medical electricity occupies a good half of the book and

may be said to be as complete an exposition of the theory and practice of this branch of medicine as there exists to-day. The theories of the principles of static and dynamic electricity are made most clear by the use of tables and diagrammatic charts; all necessary equations are printed so that they seem, at least at first glance, not too complicated. In short, this part of the volume is adapted admirably for the use of him who has not the theoretical training of an electrical engineer, but is called upon to use in practice the forces of electricity as therapeutic agents.

Dr. Tousey's ability to deal clearly with matters more abstract in nature has empowered him lucidly to present the involved theories of the Röntgen rays. In his consideration of certain practical applications of them, on the other hand, he is confusing, to say the least, to the seeker of information. He has, for example, inaugurated a scale of intensity of x-radiance, for the unit of which he has contributed his own name. The use of so arbitrary a unit, in comparison with the generally accepted units of Kienbock, Sabouraud and Noire, Benoist or Walter, will naturally be confusing and uncertain until it shall have become accepted by some scientific body of Röntgenologists.

The author's illustrations of his Röntgenographic work in some of the more modern fields, for instance, the stomach and intestines, are disappointing, and we find it hard to become enthusiastic over the effect of the use of the Tousey cylinder and diaphragm upon the radiographic results.

In his consideration of the radiography of the mastoid cells, he makes no reference to the published work of Lange, who has devised the best technic in this branch of the work.

Dr. Tousey's illustrations on teeth are admirable, although his technic, as he describes it, exposes the operator unnecessarily.

With a few exceptions, the list of references to the literature is a complete one, and these, together with the admirable index, show much care in their preparation.

*The Modern Treatment of Alcoholism and Drug Narcotism.* By C. A. McBRIDE, M.D., L.R.C.P.& S. (Edin.) New York: Rebman Company. 1910.

This book, though not particularly well written, presents an interesting study of inebriety as a disease, its pathology, causes, forms and treatment. The author's method of dealing with alcoholism is by a combination of diet, drugs, hydrotherapy and moral suasion. He outlines the routine course of this treatment, with description of its more important variations according to the type of the disease. He also discusses the travel cure, the fruit cure and the restraint cure, with special sections on the treatment of delirium tremens and alcoholic trance. There is brief consideration of the nature and treatment of morphinism and of ether, chloroform, tea, coffee and opium inebriety. The volume seems a useful contribution to a very important subject, representing, as it does, the results of thirty years successful personal experience in the treatment of alcoholic and drug inebriates.

*Those Nerves.* By GEORGE LINCOLN WALTON, M.D. 12mo. Pp. 203 with a portrait of Marcus Aurelius. Philadelphia and London: J. B. Lippincott Company. 1909.

"Certain subjects introduced in a previous publication will bear further elaboration," says the writer in his preface, adding that long-standing faulty mental habits are to be modified only by reiteration and repeated presentation of useful suggestions. The author, therefore, takes up various forms of morbid mental activity, pointing out the evil effects and the lack of any actual benefits which such obsessions and morbid fears bring about, and giving wholesome advice as to healthy modes of thinking. The consideration of these conditions is enlivened by many apt quotations and touches of humor, and the author's attitude is characterized by the same good sense and avoidance of psychic obscurity that was so noticeable in "Why Worry?" In the present volume, however, there is some tendency toward somewhat far-fetched comparisons and too much of a disposition to regard all aversions, fears and depressions as simply obsessions which indicate a psychasthenic state, without sufficient allowance for normal mental reactions. Nevertheless the advice is sound and may sometimes be of benefit, were it not for the fact that the numerous quotations from Epictetus remind us that sound advice has been given to mankind for many centuries, and that few of those who need it are disposed to follow it.

*Fractures and Separated Epiphyses.* By ALBERT J. WALTON, F.R.C.S. (Eng.), M.S. (Lond.), L.R.C.P., M.B., B.Sc. (Lond.), Surgical Registrar, London Hospital. New York: Longmans, Green & Co. London: Edward Arnold.

Frequently it occurs that the painstaking reviewer finds upon his desk a book which is excellent but offers little for comment, — a book dealing soundly with well-known important topics which must be studied by all undergraduates as well as by general practitioners. The book now under review is a case in point.

It is an admirable production of 288 pages and presents lucidly, though somewhat briefly, the topic of fractures. As Walton says in his preface, "Students and those first commencing hospital appointments have often mentioned to me their need of a small book dealing with the more practical aspects of fractures. This book is an attempt to supply such a want." He supplies it very well indeed. He discusses various aspects of fractures, for the book is not a mere compend of treatment. There are numerous x-rays, photographs and sketches which illustrate well the subject. We heartily commend the work.

THE BOSTON

# Medical and Surgical Journal.

THURSDAY, MARCH 9, 1911

*A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 810 Paddock Building, 101 Tremont Street, Boston.*

*All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.*

*Remittance should be made by money order, draft or registered letter payable to*

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

## REPORT OF THE COMMISSION ON FACTORY INSPECTION.

THE report of the Massachusetts State Commission appointed last year to investigate the general subject of the inspection of factories, workshops and other establishments was recently submitted to the legislature.

We shall limit our review of the report to that portion which deals with the health inspection carried on under the State Board of Health and comment on the Commission's conclusions and recommendations in so far as they affect the work of that board. The Commission's report on the work of the State Inspectors of Health is in many ways misleading, in some respects inaccurate and is quite inadequate. In a section devoted to the "Inspection Service of the State Board of Health" the organization of that service is described at length and considerable detail is given as to the printed forms used, the manner of submitting reports and records to the main office, and the methods of filing cards, but no statement can be found about the actual work done by the State Inspectors of Health, including the changes made to improve the sanitation of factories and workshops as the result of issuing recommendations or orders.

To one who is unfamiliar with the work of the State Inspectors of Health the impression might readily be gained that these physicians are giving a limited number of hours per week to the state and that "the chief work that the inspectors are now doing consists in the collection of data relating to industrial hygiene or occupational diseases." The Commission hasten to add that they "would say nothing in derogation of the value of this study to the human race, and more particularly to that part of the working class engaged in so-called unhealthy occupations," and that this work "would, if carried on in the future, prove of great value to the working population of the Commonwealth." The impression is thus given that these physicians who give a limited number of hours to the state are engaged principally in some sort of an academic investigation which will ultimately prove of some value to the human race. Now what are the facts? The majority of the State Inspectors of Health, particularly those in the industrial districts, give the greater part of their time to the work. Many of the men average from six to eight hours daily, a good deal more time than could reasonably be expected from some of them considering their salaries. The chief work in which these physicians are engaged, "the collection of data relating to industrial hygiene or occupational diseases," is not an academic investigation without immediate practical value, but is the only kind of health inspection worthy of the name. Efficient inspection cannot be carried on in a routine manner. The only purpose of inspecting the sanitary conditions in industrial establishments is to safeguard the health, first, of the workers and, second, of the community at large. The study of occupational hygiene in each establishment consists of a careful study of all the influences in that establishment which may be injurious to the health of the workers. Such a study involves a knowledge of the sanitary conditions, including the adequacy of lighting, ventilation and cleanliness, of the establishment, as well as some knowledge of the various industrial processes in which the operatives are engaged. This work in every instance leads to practical results: if any unsanitary conditions are found, if any processes are conducted wherein employees are exposed to injurious influences, orders are issued, or, in case no specific statute covers the case, recommendations are made to provide for the necessary changes. The data relative to occupational diseases are of the utmost practical immediate value, for how can we know what processes must be protected, what processes are dangerous, unless we learn the effects on the health of the operatives engaged in these processes?

The criticism that at the present time there is little system, "that health inspectors in some cases visit the same establishment several times during the year and other establishments not at all," is based upon a superficial knowledge of the inspectors' work, and is answered in the Commission's summary when they refer to the

policy of the State Board of Health as that of encouraging "intensive work in the part of the field actually covered, rather than to attempt to cover the entire field in superficial and ineffectual fashion." And it is just because the work is done in such a thorough and systematic manner that in several of the districts a "single round" of the district has not yet been completed.

It is quite true that the State Inspectors of Health might to great advantage have non-medical assistants for some of the routine work, but such inspectors could not take the place of men trained in the science of hygiene and preventive medicine. Some of the most valuable work which the State Inspectors of Health have done has been along the line of education of both employers and employees. This work, while it does not lend itself to tabulation, is none the less valuable, and could not be done by non-medical men.

We have said that the report is in some respects inaccurate; two examples will suffice: (1) Among the criticisms reported as brought before the Commission is one that "no department professes to inspect toilets in factories, workshops" and "mercantile establishments . . . for their sanitary condition," and this criticism, notwithstanding the fact that the State Inspectors of Health are legally authorized to make such inspections, and that more than one thousand new toilets have been installed as the result of their efforts. (2) In the supplementary suggestions the report says: "The lack of authoritative information regarding the number and location of factories, workshops and mercantile establishments, especially tenement workrooms, leaves many loopholes for evasion of the labor laws. It would seem to be the first task of a board entrusted with the administration of these laws to inform itself concerning the exact extent of the field in which its work lies; and this task involves registration of all industrial establishments under its jurisdiction." The report also states that at present there is no complete list of industrial establishments in any district in the Commonwealth. Here again we see the lack of thorough acquaintance on the part of the Commission with the work of the State Board of Health. The fact is that in many districts the State Inspectors of Health have made a complete registration of all factories and workshops. Moreover, all the tenement workrooms throughout the state are, practically speaking, completely registered; while in the Suffolk County district, where there are about fifteen hundred of these workrooms, all are carefully registered and indexed so that the number of the workrooms in any street or any building in the district can be had on reference.

The conclusions and recommendations of the Commission, based upon their own findings and criticisms, are not justified. In spite of the superficial manner in which the work of the State Inspectors of Health was dealt with, "the members of the Commission recognize that the work of health inspection in manufacturing and mercantile establishments has been efficiently organized and directed under the State Board of Health, and that valuable results have already been achieved in this field." At the same time, the Commission find that "the factory inspection as at present conducted by the inspectors of the district police is ineffective." The Commission reason, however, from these two premises that unless a new board of industrial inspection is created to carry on the factory inspection work now done by the district police, and the medical inspection of factories supervised by the State Board of Health, "the dual control which is chiefly (?) responsible for the unsatisfactory working of the present system would still exist."

If, as is alleged, the present apportionment of duties and powers between the two staffs of inspectors is "complex and confusing," the legislature can remedy the situation by a far less radical and more economical way than by the creation of a new bureau. The argument that the entire service of inspection could be directed and organized more economically under one head is not convincing. The creation of four offices to be occupied by high salaried officials, the appointment of seventy-six inspectors instead of the present force of forty-two, and, in addition, the organization of a new office force, can hardly be considered an economic venture for the state. But even if a bureau of industrial inspection were created, there is nothing in the Commission's report, assuming all criticisms of the existing health inspection to be valid, that would justify the conclusion that there is need of transferring the health inspection work of the State Board of Health to such a board. The many valid reasons why such an important branch of the public health service as the health inspection of industrial establishments should not be taken from the central health authority of the state have been made clear in the reports and bulletins published from time to time by the State Board of Health to which we have frequently called the attention of our readers.

Moreover, it is noteworthy that the commis-

sioner of the Chicago Department of Health, recognizing the system of medical inspection of factories as organized by the Massachusetts State Board of Health, and the fact that Massachusetts has done more than any other state in the way of sanitary inspection, in a late bulletin relating to the state of Chicago's health, says: "It is to be hoped that both the city and state will at no distant day through proper legislation incorporate and put into thorough working shape a public service of this kind."

## PHILANTHROPY, MEDICINE AND THE LIMITATION OF FAMILIES.

In an editorial on "Large and Small Families" in the issue of the JOURNAL for Feb. 16, we commented on some differences of opinion in regard to the desirability of unlimited procreation among the poorer classes of the community. In the March number of the *Popular Science Monthly* is a thoughtful though somewhat pessimistic article on "The Social Problem," by Prof. John J. Stevenson, of New York University, in which, after analyzing and summing up the social and economic evils of American civilization, the author states his opinion that the only alleviation for these conditions lies in the restriction of immigration and the limitation of offspring among the poor.

"The early settlers of this land had large families," he says, "and the children were strong physically and mentally. But they were a fine stock, and, like all pioneers, they were the best of their race — and natural selection came to their aid. . . . No such selection exists in the class under consideration [the immigrant poor in large cities], which, unfortunately, lacks the original physique. More than that, pure food laws, sewerage, proper construction of houses, sanitary regulations and the rest antagonize the operations of natural laws, whereby the sins of the parents are visited upon the children. Those who, under former conditions, would have died in infancy, now survive the perils of the earliest years, in increasing proportions reach maturity, marry and reproduce themselves — a menace to the health and well-being of the community. . . . Philanthropic work, in endeavoring to ameliorate the pangs of poverty, begins at the wrong end; instead of trying to abolish poverty, it labors incessantly to increase it and its burdens. The improvident class procreates recklessly, and would-be philanthropists encourage the folly. . . . Tenements are made better every year to protect the careless against their own negligence; public schools are inspected that contagious diseases may be checked; vaccination is compulsory and free; women in confinement have free medical attendance and diet kitchens provide proper food for them. . . . Everything within the range of possibility has been suggested or attempted in order to free the improvident from all sense of responsibility for their offspring. . . . Philanthropy should begin its work at the other end. . . . Instead of encouraging heedless procreation, its efforts should be to encourage restriction. The duty of parents to children should be made plain to those who are unwilling to recognize them; and indiscriminate free medical treatment should be abolished. . . . Marriage of persons mentally or physically defective should be illegal, and increase of the criminal or vicious should be made impossible by aid of the surgeon."

Professor Stevenson's arraignment of modern philanthropy is severe; but his recognition of conditions is clear-sighted, even though one may not concur with his suggestions of remedy. Of course he does not mean to abate the beneficent activities of sanitation and hygiene and preventive medicine. For though no doubt much modern charity and so-called social service is meddlesome and misdirected, and though it often seems that medical science merely makes possible the survival and increase of the unfit, it must be remembered that many of these measures also improve the environment of the fit and become for them important means of advance and of self-protection. Whether one agree or disagree in whole or in part with Professor Stevenson's views, however, their expression is valuable as a serious statement of certain aspects of a great problem which more and more is forcing itself on public consideration, and which deserves as well the attention of the medical profession.

## THE GROWTH OF AMERICAN UNIVERSITIES.

In the issue of *Science* for March 3 is a summary of the registration returns for Nov. 1, 1910, of twenty-seven of the leading universities in this country. Four of these — Harvard, Iowa, Indiana and Virginia — show a decrease in the total enrollment from last year, and four — Columbia, California, Minnesota and Wisconsin — show a gain of 500 or over. The largest gain was by Columbia, 1,279, or 796 if the summer attendance be omitted. Columbia now has a total registration of 7,411 students. A year ago the order of

the ten largest universities was Columbia, Harvard, Chicago, Michigan, Cornell, Pennsylvania, Illinois, Minnesota, Wisconsin and California; now it is Columbia, Chicago, Michigan, Harvard, Pennsylvania, Cornell, Minnesota, California, Wisconsin and Illinois, or, omitting the summer enrollment, Columbia, Minnesota, Michigan, Pennsylvania, Harvard, Cornell, Illinois, California, Wisconsin and New York. This rating, of course, includes all departments. If the undergraduate academic departments alone be considered, the order is Harvard, Michigan, California, Wisconsin, Minnesota, Chicago, Syracuse, Columbia, Yale and Princeton; or, including male academic students only, Harvard, Michigan, Yale, Princeton, Wisconsin, Chicago, Columbia, Cornell and Minnesota. The total enrollment of scientific students is considerably smaller than in the previous year.

In law and medicine there has been a decrease in the total number of students. The largest gains in law have been made by Stanford, Columbia and Harvard, the greatest losses by Virginia, Yale and Texas. In medicine, the greatest gains have been by Western Reserve, California and Johns Hopkins, the largest losses by Northwestern, Pennsylvania and Iowa. The present numerical order of the largest six law schools is Harvard, Michigan, New York, Minnesota, Columbia and Pennsylvania; that of the medical schools in Illinois, New York, Northwestern, Pennsylvania, Tulane, Johns Hopkins, Michigan, Columbia and Harvard.

The significance of these figures and ratings seems to be that in general the drift of education, like that of population, is towards the West, though a few of the large eastern colleges continue to hold their own or even to gain in academic enrollment. Among the professional schools the tendency is less sectional, but rather towards the development of prestige in individual schools regardless of location. For their future no one

"Can look into the seeds of time
And say which grain will grow and which will not."

## ANNUAL REPORT OF THE CARNEGIE FOUNDATION.

THE Carnegie Foundation for the Advancement of Teaching is fulfilling its promised purpose to become not merely an agency for the relief of individual teachers, but a central organ of criticism, of education throughout the country. The recently published fifth annual report of its president and of its treasurer contains, among other material, the comment of the former on "Medical Education in the United States and Canada," printed last fall as Bulletin Number 4 of the publications of the Foundation.

In this comment Mr. Pritchett points out that although the bulletin aroused objections, these were not directed against its statements of fact. Two kinds of medical school, the commercial school and the routine school, he declares, have become anachronisms in American education, and sooner or later, he believes, must cease to exist. The modern medical school must be one of ideals. "The medical practitioner of these opening years of the twentieth century should be an educated man, his conscience sensitive to the social importance of general physical well-being, his intelligence quick to follow the progress of medical education. Such mind and character grow up naturally amid the stimulating influence that universities and institutions of research produce."

In the issue of *Science* for March 3, there is a summary of the Carnegie Report, and also a critical review of it by Mr. Cattell, who points out that the addition this year of three more universities to the accepted list of the Foundation raises a question of policy in its attitude towards state-supported and sectarian institutions of learning, and also the question of the adequacy of its income to meet the new demands that will be made upon it. Mr. Cattell also disapproves the method of action of the Foundation in discontinuing its pensions for length of service, though he does not regret what he believes will be the ultimate necessity of giving up the retiring allowances for age and confining them to retirement for disability.

At the seventh annual conference of the Council of Education of the American Medical Association, which was in session last week at Chicago, there was also considerable adverse criticism of the bulletin of the Foundation on "Medical Education in the United States and Canada," to which we have above referred. Whatever may be said of the financial policy of the Foundation, however, Mr. Pritchett's defense of this bulletin seems adequate; and the standards of medical education and of personal quality which the Carnegie Foundation holds up for our profession seem worthy of individual and collective effort to approach and ultimately to attain.

## FOUR RECENT HOSPITAL REPORTS.

THE thirty-third annual report of the trustees of the Danvers (Mass.) State Hospital for the year ending Nov. 30, 1910, chronicles numerous

changes during that year in the medical staff, among them the resignation, on June 30, of Dr. Charles W. Page, who had been superintendent of the institution for nearly eighteen years, and who has been succeeded by Dr. Harry W. Mitchell, formerly superintendent of the Eastern Maine Insane Hospital. Dr. Mitchell's appended report shows that during the year ending Sept. 30, 627 new cases were admitted and 568 cases were dismissed, leaving a total of 1,483 patients in the hospital on Oct. 1, 1910, as against 1,424 a year previous. Of the 209 deaths that occurred among inmates during the year, nearly one half were due to general paralysis and organic dementia. During the year five nurses were graduated from the hospital training school.

The forty-sixth annual report of the trustees of the Boston City Hospital for the year ending Jan. 31, 1910, has only just been published, on account of the great accumulation of unfinished work at the city printing department. It includes the report of the superintendent upon the hospital and its various branches and departments, and also the medical and surgical statistics for the year, the house rules, and the rules for admission, discharge and government of patients. During the year 135,992 visits were made to the out-patient department by 39,482 patients; at the South Department, 3,123 patients were treated; at the Haymarket Square Relief Station, 35,771; at the East Boston Relief Station, 8,450, and at the Convalescent Home in Milton Lower Falls, 357. The total number of patients admitted during the year to the hospital wards was 8,950. The report is interestingly illustrated with a series of several plates and two large maps, and contains abundant and instructive statistics, showing the range and extent of service to the community done by the largest general hospital in New England.

The eighty-fifth annual report of the Massachusetts Charitable Eye and Ear Infirmary for the year 1910 includes the reports of the board of managers, of the treasurer, of the superintendent, of the board of surgeons, and of the pathological laboratory. During the year 3,432 patients were admitted to the infirmary wards, and 28,906 new cases applied for treatment in the out-patient department, and 35,203 old patients were treated. Nineteen nurses were graduated from the training school and 21 were received for the post-graduate course. The importance of open-air treatment for all hospital patients is now so generally recognized that the managers earnestly appeal to the public for subscriptions towards the sum of $10,000 to enable the construction of a roof garden for this purpose on the present hospital building.

The ninety-seventh annual report of the trustees of the Massachusetts General Hospital for the year 1910 includes the reports of the General Hospital in Boston and the McLean Hospital and the Convalescent Hospital in Waverley, Mass. The report of the trustees chronicles the establishment at the General Hospital during the year of a Children's Medical Department, a Dental Clinic and a Genito-Urinary Department. The report of the administrator calls attention to the need of a new Administration Building, of a new ward building, and of a country branch for convalescent surgical cases, and to the desirability of establishing a private hospital in close connection with the General Hospital. During the past year the number of patients admitted to the wards was 6,092; 22,302 new cases were received in the Out-Patient Department, to which a total of 124,584 visits was made. In the McLean Hospital at Waverley 166 new patients were admitted and 168 were discharged. The total number of patients admitted to the Convalescent Home was 638. Other reports and data, maps and illustrative plates complete a valuable and interesting volume.

These four annual reports, of four large and important medical charitable institutions, with their various branches in and near Boston, emphasise the extent and variety of the work done in the study and relief of human suffering, a work which makes our community one of the great centers of medical progress in this country.

## THE WORK OF THE FLOATING HOSPITAL.

In our issue of last week we published a series of papers under the general heading, "Studies in Intestinal Disturbances in Infants," without a sufficiently definite statement that these papers were all the result of work done on the Floating Hospital by its staff during the season of 1910. We are glad, therefore, to call attention to the fact that quite apart from its purely utilitarian uses as a means of supplying fresh air and healthful conditions for infants during the hot months of summer, the Floating Hospital has admirably served the broader purpose of providing a valuable means of investigation of the various affections to which infants are liable. The staff has shown a commendable enthusiasm in prosecuting these researches, and in carrying them to a conclusion as a collective piece of published work.

## MEDICAL NOTES.

A CENTENARIAN. — Mrs. Mary Wray, a negress, who died at Seattle, Wash., on March 3, is alleged to have been born in February, 1807, in Virginia. In her girlhood, as a slave, she is said to have worked on the construction of the first railroad built in Tennessee.

BUBONIC PLAGUE IN VARIOUS CITIES. — Report from St. Petersburg states that the epidemic of bubonic plague is still causing many deaths daily at Harbin, Kirin, Hulanchen and Bodune in Manchuria. A single case of the disease is reported to have occurred on March 4, at Odessa, a Russian port on the Black Sea. During the fortnight ending Feb. 25, there were six deaths from bubonic plague and five from smallpox in Amoy, a Chinese seaport on the Straits of Formosa, north of Hong Kong.

CHOLERA AT HONOLULU. — In last week's issue of the JOURNAL we noted the occurrence of two cases of Asiatic cholera at Honolulu. Report from that city on March 5 states that up to that time there had been 19 cases of the disease, with 15 deaths. All the patients were native Hawaiians. The quarantine established by the Territorial Board of Health has been extended, and the crews of visiting steamers will not be allowed to leave their ships while in port. A special committee has been appointed to investigate sanitary conditions in the city.

INCREASE OF POPULATION IN GERMANY. — Completed figures of the recent German census show that the total population of the empire is now 64,896,881, as against 60,641,278, a net increase of 4,255,603, or approximately 7% in the past five years. Since 1885 the annual rate of increase of population in Germany has not fallen below 1%. In 1900, it was 1.5%, and in 1905, 1.45%. These figures emphasize the fact that the Teutons remain to-day the most prolific as well as perhaps the most vigorous of modern civilized peoples.

AGE OF RETIREMENT FOR PHYSICIANS. — It is reported from Paris that in awarding damages to a French physician recently for injuries and consequent loss of practice sustained from being run into by an automobile, the court added the comment that at the plaintiff's age, sixty-five, a doctor should be glad of the opportunity to retire from practice. However this may be, such a method of retirement would seem less agreeable than a compulsory age limit.

AN EARLY WOMAN MEDICAL STUDENT. — An item in the London *Globe* states that one of the earliest women students of medicine was a Maltese lady who in the eighteenth century, under the patronage of the Knights of Malta, was enrolled in the Florence School of Medicine. During the period of her study she boarded and lodged with the nuns of a neighboring convent. She was allowed to witness and assist in the operations on female patients in the Majeur Hospital, received some private lessons at the convent from Professor Mannoni, but was not permitted to attend the lectures given to male students. It is not stated whether she was ever given a medical degree or whether she subsequently practiced her profession.

SOME RECENT GIFTS TO HOSPITALS. — The will of the late Mrs. Leander S. Cole, who died on Feb. 4 at Kingston, Mass., was filed in probate at Plymouth, Mass., on Feb. 28. Among numerous charitable bequests, it contains one of $100,000, without restriction, to the Jordan Hospital, Plymouth, which is also made the residuary legatee of the estate.

The will of the late Mrs. Benjamin D. Hicks, of Old Westbury, Long Island, who died on Feb. 17 in New York City, was filed in probate on March 1, and contains a bequest of $100,000 to the Nassau Hospital Association of Mineola, L. I.

Report from London states that Mrs. Whitelaw Reid, now resident in that city, has made an additional gift of $60,000 to the Red Cross Guild Hospital at San Mateo, Cal., to be used in the construction of new buildings. Mrs. Reid established this hospital a few years ago as a memorial to her parents.

### BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Feb. 28, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 35, scarlatina 41, typhoid fever 2, measles 16, smallpox 0, tuberculosis 42.

The death-rate of the reported deaths for the week ending Feb. 28, 1911, was 19.23.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Feb. 25, 1911, was 280, against 279 the corresponding week of last year, showing an increase of 1 death, and making the death-rate for the week, 21.19. Of this number 151 were males and 129 were females; 275 were white and 5 colored; 150 were born in

the United States, 119 in foreign countries and 11 unknown; 51 were of American parentage, 196 of foreign parentage and 33 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 42 cases and 5 deaths; scarlatina, 33 cases and 3 deaths; typhoid fever, 3 cases and 1 death; measles, 70 cases and 0 deaths; tuberculosis, 57 cases and 18 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 51, whooping cough 4, heart disease 34, bronchitis 4. There were 30 deaths from violent causes. The number of children who died under one year was 41; the number under five years, 51. The number of persons who died over sixty years of age was 81. The deaths in public institutions were 118.

Fire at Melrose Hospital. — There was a slight fire last week in the laundry building of the Melrose (Mass.) Hospital, accidentally set by a child playing with matches. The damage amounted to about fifty dollars.

Meeting of Cambridge Nurses. — The seventh annual meeting of the Cambridge Visiting Nursing Association was held in Cambridge, Mass., on March 6. Addresses were made by Miss Clark, Miss Woodworth and by Dr. Eliot.

Fine for Violation of Pure Drug Laws. — In the United States District Court last week, a Boston firm of manufacturing chemists pleaded guilty to a charge of selling a certain "compound cordial" in violation of the pure food and drug laws, and was fined $25.

Appointment of Dr. Shay. — It was announced on Feb. 27 that Dr. Charles E. Shay, of Roxbury, had been appointed a school physician, to fill the vacancy caused by the recent resignation of Dr. Silas H. Ayer. Dr. Shay is an assistant physician at the Boston Consumptive Hospital.

A Living Centenarian. — Mrs. Jacob Morrell, of Newburyport, Mass., who is said to have been born at West Newbury, Mass., on March 1, 1809, celebrated last week the supposed one hundred and second anniversary of her birth. She has had ten children, of whom three sons and one daughter are still living. She also has twelve living grandchildren and nine great-grandchildren. Mrs. Morrell, who is in excellent health, has been a widow for many years.

Increase of Opium and Cocaine Habits. — At the thirty-third annual public meeting of the New England Watch and Ward Society, held in Boston on March 5, addresses were made by Dr. Charles W. Eliot and by Dr. William F. Boos, of Boston. Dr. Boos spoke of the increasing use of opium and cocaine by habitués in this community, of its relation to crime, and of measures that should be adopted to check its further spread. The annual report of the secretary showed that during the past year the society had secured in New England seventy-seven convictions for illegal sale or use of these drugs. Dr. Clarence J. Blake, of Boston, was elected vice-president of the society for the ensuing year.

Anti-Vivisection Exhibit and Lecture. — In the issue of the Journal for Feb. 23 we published a preliminary notice of an exhibit in Boston by the New England Anti-Vivisection Society, and of a lecture before that body by Dr. Herbert Snow of England. It is now definitely announced that this lecture will be given in Lorimer Hall, Tremont Temple, next Monday, March 13, at 8 P.M. "Admission is entirely free." The anti-vivisection exhibit is to be held in Gilbert Hall, Tremont Temple, from March 13 to 18, inclusive, and will be open from 10 A.M. to 10 P.M. "No one can afford to miss this exhibit," says the announcement, "it has accomplished wonders for the cause wherever held." Both the lecture and the exhibit should prove interesting and instructive, from various points of view, and we believe it desirable, as we stated in our previous note, that they "should be attended by physicians interested in the safeguarding of legitimate animal experimentation."

The Sharon Sanatorium. — The Sharon Sanatorium at Sharon, Mass., one of the pioneer institutions in the hospital treatment of tuberculosis in this country, and the first in New England, is entering the twentieth year of its existence. Its purpose is to offer the hope of recovery to women of very limited means afflicted with the disease in its incipient form. It is intended for the class who, while unable to afford the prices of the more expensive sanatoria, yet need the privacy and close supervision not easily obtainable in large public institutions. It is dependent largely upon public support, the price of board being quite inadequate to meet the current expenses.

In order appropriately to signalize the twentieth anniversary of the sanatorium, a public meeting will be held in Huntington Hall, Massachusetts Institute of Technology, Friday, March 17, at half-past four. At this meeting Hon. Curtis

Guild, Jr., will preside, and Dr. Livingston Farrand, of New York, executive secretary of the National Association for the Study and Prevention of Tuberculosis, will make the chief address on the subject, "The Present Outlook in the Campaign against Tuberculosis." Dr. Arthur T. Cabot, president of the Massachusetts Tuberculosis Commission; Dr. Herbert M. King, superintendent of the Loomis Sanatorium at Liberty, N. Y.; Prof. William T. Sedgwick, president of the directors of the Sharon Sanatorium, and Dr. Vincent Y. Bowditch, medical director of the Sharon Sanatorium, will also speak on the general subject. A cordial invitation is extended to all interested in the movement for the suppression of tuberculosis to attend the meeting.

### NEW YORK.

Mumps at Cornell. — Parotitis has been epidemic at Ithaca, N. Y., where there were reported to be 35 cases among students at Cornell University.

A Cold Storage Bill. — On Feb. 21, the Jersey Assembly passed a cold storage bill which prohibits the storing of foodstuffs for a longer period than six months without the consent of the State Board of Health.

Centenarians. — Mrs. Bella Goldberg, a native of Russia, died at her home in New York on March 1, at the reputed age of one hundred and seven years. Her husband, ninety-seven years old, is a peddler and still active. She leaves five children, twenty-seven grandchildren and six great-grandchildren.

Mrs. Jane Beam died in Paterson, N. J., on March 3, in her one hundred and third year. She was born at Ramapo, N. Y., in 1808, and had been a widow twenty-seven years.

German Hospital. — The annual meeting of the German Hospital and Dispensary was held on Feb. 20, when the report of the board of trustees showed that during the past year $67,771 had been received in donations and bequests, and that Mrs. Anna Woerishoffer had now given $100,000 towards the establishment of a children's department. Clinical instruction, it was announced, will be given hereafter in the wards of the hospital to Columbia University medical students. During the year, 45,703 patients were treated, of whom 6,490 were treated in the hospital proper, 32,845 in the dispensary department, and 3,724 by visiting district physicians. In the accident department 2,643 persons were treated.

Report of the City Health Department. — The condensed quarterly report of the City Health Department, for the quarter ending Dec. 31, 1910, shows that there was a decrease in the total number of deaths from the average of the preceding five years of 1,444, and in children under five years, 765. The largest decreases from the quinqennial average were in apoplexy and softening of the brain, 329; pulmonary tuberculosis, 282; bronchopneumonia, 174; and Bright's disease and acute nephritis, 167. The largest increases over this average were in organic heart diseases, 70; chronic bronchitis, 37; and appendicitis and typhlitis, 21.

Control of Venereal Diseases. — An important meeting of the American Society of Sanitary and Moral Prophylaxis was held at the New York Academy of Medicine, on Feb. 23, when the general subject of discussion was Health Department Control of Venereal Diseases, a matter which is now being favorably acted on by the Academy of Medicine, the New York County Medical Society and the City Health Department. The following papers were read: "Venereal Diseases should be Reported," by Dr. Frederic H. Gerrish, of Portland, Me., professor in Bowdoin College; "Why the Ophthalmologist Believes that Venereal Diseases should be Reportable," by Dr. Lucien Howe, of Buffalo; "From the Legal Standpoint," by William A. Purrington, formerly counsel to the Medical Society of the County of New York; and among those who took part in the discussion were Dr. H. M. Biggs, general medical officer of the Health Department, and Drs. William M. Polk, A. Jacobi and L. Duncan Bulkley.

New Building for Sloane Maternity Hospital. — The new building for the Surgical Department of the Sloane Maternity Hospital of Columbia University was opened for inspection on March 1. This, like the rest of the hospital, is the gift of Mr. and Mrs. William D. Sloane, and cost, with its equipment, more than $200,000. It is eight stories high, fireproof, and constructed of red brick and granite, in harmony with the hospital buildings. The operating amphitheater is entirely of marble and tiling. Prof. E. B. Craigin will be in charge, assisted by Dr. Frank Oastler. Dr. E. C. Lyon is the resident instructor in gynecology and Dr. Wilbur Ward, resident instructor in obstetrics.

Medical Conferences. — A series of medical conferences, arranged by the Educational Alliance

with the endorsement of the executive bodies of the New York County Medical Society and the Academy of Medicine, is being held during March and April in the auditorium of the Alliance, on East Broadway, presumably for the benefit of the large body of practitioners on the lower East Side. Some of the lecturers and subjects are as follows: Dr. J. O. Polak, on "Medical and Legal Aspects of Abortion"; Dr. J. Pedersen, "Sanitary and Moral Prophylaxis"; Dr. A. A. Berg, "Lodge and Contract Practice"; Dr. W. M. Polk, "Medical Ethics and their Application to Practice"; Dr. J. Bretauer, "The Secret Division of Fees"; Dr. S. S. Goldwater, "Abuses of Hospital and Dispensary Practice."

Anniversary of Bellevue Hospital Alumni. — The twenty-fifty anniversary of the Society of the Alumni of Bellevue Hospital was celebrated at Delmonico's on Feb. 28, when Dr. Floyd M. Crandall, president of the society, acted as toastmaster and addresses were made by Chief Justice of the Court of Special Sessions and Drs. Stephen Smith; Charles F. Stokes, Assistant Surgeon-General, U. S. N.; William M. Polk, Joseph D. Bryant and John W. Brannan. Dr. Smith, now eighty-eight years old, who left the active service of Bellevue in 1851, told of the early days of the institution, when it was little better than an almshouse and the York was the only other hospital of note in the city. Fourteen out of the nineteen original members of the society now living attended the gathering, and the oldest alumnus, Dr. Starling Loving, of Columbus, Ohio, was present. He and Dr. William Dibbons, who died recently, were the first paid internes (1849–50). They did excellent service in the cholera epidemic and were presented with a set of resolutions by the board of aldermen.

Mortality Statistics. — Some interesting figures for the year 1910 are given in the last *Monthly Bulletin* of the State Health Department. Diphtheria caused 2,421 deaths, which was 125 more than in 1909, but 35 less than in 1908, 350 less than the yearly average of the past twelve years of lowered mortality, and 3,000 less than the average of the twelve years prior to that. New York City reported 17,226 cases, with 1,715 deaths, and the rest of the state, 5,400 cases, with 716 deaths; being for the former a fatality of 1 death in 10, and for the latter, 1 in 7, probably from lack of a full report of cases. In the urban population there were 32 deaths per 100,000 from this disease, and in the rural, 10. In two counties, Schuyler and Hamilton, no diphtheria occurred, and in ten other counties less than 10 cases. Scarlet fever was more prevalent than in 1909, the deaths numbering 1,616, as against 1,200; but New York City shared in the increased mortality to a less extent than the rest of the state. There were 432 fewer deaths from measles than from scarlet fever, but in eleven years of the last twenty-five the deaths from measles have exceeded those from scarlet fever, their average mortality having been annually 1,100 to 1,350. Taking into account its remote effects, measles would seem to be fully as large a contributer to mortality as scarlet fever. The reported cases numbered about 70,000, more than one half of which were in New York City. Pneumonia caused 9,843 deaths, 450 more than in 1909 and 1,200 more than in 1908, but fewer than in the years preceding. Bronchopneumonia, with 7,240 deaths, and acute bronchitis, with 1,600 deaths, were chiefly fatal in March, and during the annually recurring epidemic of influenza, which disease was given as the direct cause of 1,439 deaths. March, on this account, was the month of highest mortality, the number of deaths exceeding those in July by 400. The average midwinter mortality was 418 deaths daily, while the midsummer was but 400.

Dr. Herbert Snow and Anti-Vivisection. — Dr. Herbert Snow, the English anti-vivisectionist, has been giving two lectures before the New York Anti-Vivisection Society. His special message here, as elsewhere, has been the uselessness of the modern era of the experimental study of cancer, yet Prof. James Ewing, of the Cornell Medical College, in a published letter, points out that in his testimony before the Royal Commission on Vivisection he not only acknowledged, but displayed, gross ignorance of the objects, methods and results of this study. Although positively asserting his heterodox opinion that Jensen's mouse tumor, which is now being propagated by scientific students of cancer in every civilized country, has nothing in common with the cancer of human beings, he admitted that he had never seen a mouse tumor and knew nothing about the diagnosis of cancer in lower animals. Though Dr. Ewing shows up his inconsistencies and errors with convincing force and in considerable detail, he is disposed to regard Dr. Snow, whom he speaks of as in many respects a quaint and interesting character, with a feeling of pity. His advancing years, which he pleaded in 1906, may excuse him,

he says, for not looking more carefully into the quality of the auspices under which he visits America, and he may not know that the New York Anti-Vivisection Society, whose hospitality he accepts, stands convicted in this country of gross and persistent misrepresentation of the truth. Dr. Snow having published a violent and contemptuous diatribe in reply to Professor Ewing's criticisms, the latter has, with his characteristic directness, completely refuted his misstatements and concludes his answer with these words: "As for attacking a medical confrère, I think the medical profession will support me in asserting that Dr. Snow's statements about the worthlessness of animal experimentation have effectually removed him from the protection of professional courtesy, as well as from the further consideration of all sensible persons."

Congestion of Population. — The Commission on Congestion of Population appointed by Mayor Gaynor last May made its report on Feb. 28. This is very voluminous, covering several hundred pages and including one hundred tables showing various comparisons, from which deductions are drawn. It is divided into five parts, dealing with conditions of room crowding, the effects of such conditions of living on morals, health and mortality, the causes of the overcrowding, the methods adopted by European cities to prevent similar conditions, and recommendations for means of relief. Almost all the recommendations are accompanied by drafts of ordinances designed to carry them into effect The Commission points out that the present tenement-house law is defective, since under it congestion south of Fourteenth Street, Manhattan, is actually increasing. This law, allowing six-story tenements, as it does, permits a population of at least 1,300 to the acre. The increase in population density in the different boroughs from 1905 to 1910 is given, the average increase for the city being 3.5 per acre. Very serious room overcrowding was found in Brooklyn and the Bronx as well as in Manhattan. The various causes of congestion are gone into extensively, after which measures for their abolition or amelioration are taken up. A few of these are the following: No building erected hereafter in Manhattan below 181st Street should exceed the cubage or volume of 174 times the area of the lot. Elsewhere in the city no building should exceed 120 times such cubage. Every factory and loft building hereafter erected should have in the rear an open lot, extending across its entire width and in depth equal to at least one tenth its height. No tenement should exceed in height the width of the widest street on which it stands, and elsewhere than in Manhattan, except under special circumstances, tenements of more than four stories should be prohibited. In outlying districts three stories should be the limit. No room in a tenement hereafter to be erected should be less than 9 by 10 feet, and every apartment in a new tenement should have at least one room with a minimum superficial area of 150 square feet. At least 600 cubic feet of air space should be allowed for every adult, and 300 for every child under twelve years. The Commission urges that immediate steps be taken to provide more playgrounds for the city, and also that during certain hours each day some streets in congested districts should be closed so that they may be used as playgrounds.

## Current Literature.

### Medical Record.

Feb. 25, 1911.

4. Palmer, F. A. *Stock Vaccines in Acute Gonorrhea.*
5. Verbrycke, J. R., Jr. *Gastric Ulcer, Hemorrhage, Operation, General Peritonitis, Vaccine Therapy.*
6. Royster, H. A. *Melted Iodoform Ointment in the Treatment of Suppurating Bubo and Ischiorectal Abscess.*
7. *White, G. D. *Is Cancer Contagious? A Report of Five Cases with Four Deaths.*
8. Griffin, E. A. *A Case of Multiple Pregnancy with Eclampsia.*

7. White reports five consecutive cases of cancer in one family. Three lived in one house, two in another. All were related to each other by blood or marriage or both. The first case occurred in 1905, the last in 1910; the first four have died, the last one cannot live more than six months. This suggestive series recalls to the writer's mind the instance reported by Dr. Gaylord, of Buffalo, of several healthy rats developing malignant disease in a cage previously occupied by infected rats. [L. D. C.]

7. Hart, A. J. *A Simple Technic for Preparing Salvarsan in Oily Suspension.*
8. McDowell, W. *The Origin of Cancer and Its Control.*

5. Funke points out that in most cases of neuralgia there is a lesion responsible for the pain. This lesion may be near the seat of pain or at a distance from it. A limited number of cases of neuralgia are due to products of protein putrefaction in the intestine. The writer reports eight cases of obstinate neuralgia — sciatic, supra-orbital, trifacial — successfully treated by energetic purgation, sometimes supplemented by sour milk. He watched carefully the excretion of indican in these patients and found that diminished indicanuria generally coincided with mitigation of pain. [L. D. C.]

4. Dr. Craig, of the Army Medical Corps, publishes the results of his studies on the etiology of dengue and compares them with the experiments of others on yellow fever and pappataci fever. He points out the similarity between these three fevers, which suggests a close relationship between the causative organisms. All three of these diseases have a sudden onset, run a comparatively rapid course and terminate by crisis. In all three the cause is present in the blood, but only during certain periods. All three can be produced by the injection of the blood (filtered or unfiltered) of a patient. All three are transmitted by an insect — yellow fever and dengue by a mosquito, pappataci fever by a biting fly. In all three the causative agent is ultramicroscopic. There is conclusive evidence that none of the three is contagious. [L. D. C.]

4. Corbus believes that the intravenous method of giving salvarsan, on account of the rapid elimination of the arsenic, is greatly inferior to the intramuscular alkaline solution method of Alt and Lesser. Each case should, however, be treated individually with special reference to duration of infection, severity of infection and condition and age of the patient. In all early infections, i. e., those before the Wassermann reaction is present, the intravenous method is especially indicated. The value of this method decreases in direct proportion to the length of time of the infection, as in the later stages the spirochetes are not so free in the blood stream, but are held in the lesions and hence not so easily reached by the intravenous method. But when a quick action is desired, as in malignant lues, it is the only method to employ. A simple injection, speaking generally, has, in favorable cases, approximately the same result as four or five months' treatment with mercury and iodine. It may show brilliant effects in cases in which mercury and iodine have failed. Salvarsan has advanced the treatment of syphilis in a decided manner, but on account of its strong arsenic content, repeated doses may have a disastrous effect on the human organism.

8. Flexner and Clark have found that the antibodies or neutralising immunity principles can be demonstrated in the blood of patients suspected of having had a so-called abortive attack of poliomyelitis, thus proving that abortive attacks do occur. They also find that the antibodies disappear earlier from the cerebrospinal fluid than from the blood stream, where they may persist for many years. It is probable, then, that to the circulating antibodies, rather than to those locally present in the cerebrospinal fluid, are due the limitation and repair of damage inflicted on the nervous system by the infection, and the enduring protection of the body from reinfection. Hexamethylenamine appears to be successful in inhibiting infection but not in restraining an already established one. It is certain that an early diagnosis can be made by finding in the cerebrospinal fluid excess of protein, a slight turbidity and increase in white corpuscles, with absence of bacteria. The authors give great credit to the work of Osgood and Lucas in establishing the fact that the virus can live for so long a time in the nasopharyngeal mucosa after recovery from the acute stage. [E. H. R.]

3. Colyer is an advocate of treating extensive caries of the teeth in children by extraction. The two chief criticisms against this method, that the loss of power to masticate interferes with nutrition and, second, that the permanent teeth will be made irregular, he endeavors to refute by a few illustrative cases.

5. Barker believes that certain cases of ununited fracture are greatly benefited by the hyperemia treatment carried on by means of elastic bandages. He cites four illustrative cases.

6. Sibley is of the opinion that practically all chronic forms of skin disease are benefited by the hyperemia treatment before applying local remedies. His most satisfactory results have been obtained in certain long-standing cases of psoriasis. [J. B. H.]

1. The bile was sterile in less than one quarter of 89 cases examined post-mortem by Windsor. The subjects were hospital patients dying of various conditions. The organism found was usually the colon bacillus, either alone or with other bacteria. Little importance can be attached to such work, owing to the probability of post-mortem or agonal invasion from the intestine. One case, however, deserves special mention. It was that of a boy nine years old, who was not known to have had typhoid fever, and who died of tuberculous meningitis. At autopsy the Bacillus paratyphosus A was recovered from the bile in pure culture. The child was, therefore, a paratyphoid-bacillus carrier. In fourteen cases the bile was examined at the time of operation for cholecystitis. In one of these, with empyema of the gall bladder following attacks of biliary colic, the paratyphoid bacillus A was isolated. In two cases of gallstones without history of typhoid fever, the bacillus typhosus was cultivated from the bile.

2. Frew has made some interesting observations on the mode of spreading of malignant disease of the suprarenal medulla in children. He finds that the metastases differ in distribution, depending upon which adrenal is affected. Where the *left* adrenal is primarily involved, there are metastases in the aortic lymph nodes, extending up into those of the posterior mediastinum and neck, and there is usually involvement of the cranial bones. In the case of the *right* adrenal gland, there are metastases in the liver, in the lymph nodes on the upper surface of the liver, on the upper surface of the diaphragm, in the pulmonary lymph nodes, in the lungs and often in the cranial bones. Exophthalmos almost always appears first on the side on which the adrenal is diseased. He considers that these features point to metastasis by way of the lymphatics. He believes that the growths are to be classified as carcinomata. J. H. Wright, however, has recently shown [1] that some, at least, of these growths belong to the neuroblastomata.

3. By the study of alternation of the ventricle produced by ligation of the coronary arteries, Lewis confirmed the observation of Hering that the *larger* ventricular beat might correspond into the *smaller* arterial beat. Moreover, he found an explanation for this apparent paradox in the presence of simultaneous alternation of the *auricles*, the weak ventricular beat being preceded by a strong auricular contraction, so that the ventricle was well filled, and could, therefore, by a weak contraction, expel a considerable amount of blood, and, therefore, give rise to a strong arterial pulse. Lewis further demonstrated that clinical and experimental alternations are identical conditions, for he found the same changes in the electrocardiogram in both.

6. Pneumococcal peritonitis, though very rare in the adult, is met with fairly often in children. Rieschbieth's analysis of fifty-seven cases shows conclusively that the involvement of the peritoneum is always secondary by way of the blood stream, the lungs being always also implicated; infection from the intestinal tract or the genitalia can be excluded. Clinically, the condition sets in acutely, with high fever, pain, vomiting and later diarrhea. The last-named symptom is more or less characteristic of this type of peritonitis and is regarded as of toxic origin. The inflammation is always general at first, but may become localized by adhesions, with the formation of abscesses. The diagnosis may be made from the association with pneumonia, or from blood cultures. The statement that an increased fibrin network in the blood is diagnostic is incorrect, for the reviewer has found the fibrin increased in some cases of ordinary appendicitis. The prognosis is very grave, the mortality being 100% where the peritonitis remained general, and 33% in the cases where localization with abscess formation occurred. Incision and drainage offers the best prospect of cure.

3. This author has been working with salvarsan in the neutral suspension for over a year in his skin clinic and now reports on the later results in some of his cases. He does not deny in the slightest the valuable effects of this drug immediately after its use, but has been rather disappointed by its end results, as recurrences are frequent and the drug at a second time not so effective. This is probably due to the power of this class of parasites to become resistent to arsenic. He favors using mercury after the salvarsan and advises starting in at once. [C. F., Jr.]

2. Alexander concludes from a careful study of the pharmacological action of taka-diastase that this preparation should be given a trial in the large number of cases of diarrhea which can be traced to intestinal fermentation. In diarrhea of gastric origin it should be used in conjunction with hydrochloric acid. Diet is important in the treatment. Carbohydrates should be much restricted at first; rolls, bread and heavy vegetables may then be added cautiously until the patient is back on normal fare. As recovery approaches, the dose of taka-diastase is reduced, but the preparation should not be dispensed with altogether until no starch is demonstrable in the stools. [L. D. C.]

6. *Heinemann. *Contribution to the Treatment of Fractures by a Method of Nail Extension.*

1. Brandes reviews the work which Beck and a number of his own German colleagues have done in the use of bismuth paste, and endeavors to point out the reasons why some of them have had poor success.

He divides the reasons for using the paste into two large classes, diagnostic and therapeutic.

For the use of the paste for diagnostic purposes, augmented by the x-ray, he has nothing but praise, and in support of his argument cites cases where doubtful diagnoses have been greatly aided. The use of the paste for therapeutic purposes he subdivides as follows:

I. *a. Empyema fistulæ.* Brandes had five of these cases, four of which improved rapidly following the use of the paste; the other had a bronchial fistula. Brandes states that he thinks the use of the paste in the majority of these cases is preferable to a large thoracoplasty.

*b.* Fistulæ from various causes, excepting bone and joint tuberculosis such as actinomycosis of the cecum, tuberculosis of the testicle, fistulæ following amputation of the foot for diabetic gangrene, perinephric abscess, etc., seven cases in all. The majority of these had had other forms of treatment. All healed well following the paste injections.

*c.* Fistulæ from septic bones and joints — eight cases. Four of them having had radical drainage operations done, Brandes considered that the convalescence was much shortened and that the paste was a valuable adjunct to surgical treatment.

II. *Poor results in infected bone cases.* — Three of these were tubercular disease of the spine and all had advanced tuberculosis of the lungs.

Brandes noticed that there was invariably a slight rise in temperature and some diarrhea following the injection of the paste. In two of his cases there was marked intoxication owing to the retention of a pool of pus behind the injected mass, a possibility which he endeavored to eliminate by his technic of injecting. He avoided any bismuth stomatitis by ordinary care of the mouth and teeth. For the injections he uses either a catheter or a syringe with a long glass nozzle, so that he may get as far as possible to the bottom of the fistula, and then while he is injecting, he slowly withdraws the tube. The cavity to be injected is always washed as free as possible of secretions before the paste is put in.

He considers that the paste is indicated in fistulæ following empyema operations, in various resections where a large cavity is left, such as nephrectomy, the removal of sequestra, etc. For bone and joint tuberculosis, however, he does not believe it should be used until the patient is in good condition following careful hygienic treatment.

He does not agree entirely with Beck that the paste has nothing but a bactericidal action, but believes that it stimulates a ferment of the leucocytes to digest the secretions of the fistula. He offers no proof of this.

His conclusions are as follows:

(1) Beck's method of injecting bismuth paste is a marked aid in the diagnosis of fistulæ by the x-ray.

(2) By careful injections of the paste, the time of healing for even diffuse fistulæ is very much shortened.

(3) Poor results are to be expected where there is a general poor condition of the patient. Large amounts of secretion and rapid progress of the primary cause of the

disease are the usual factors in causing poor results. As stated before, bone and joint tuberculosis have the greatest percentage of failures.

(4) The method has the danger of bismuth and nitrate poisoning. By altering the technic and using bismuth carbonate for bismuth subnitrate, and by the diminution of the volume of bismuth, the danger of poisoning is practically done away with.

(5) A non-poisonous substitute of the bismuth compound which can give as good results must be discovered before the injection of a paste can cause not only the quickest and most favorable results, but also the safest in the treatment of sinuses and fistulæ.

2. Solieri devotes a great deal of space to a textbook review of the various surgical lung complications, mentioning the names of the men who have recently written on the different subjects.

He concludes with a very careful report of six cases of his own which were as follows:

Two foreign body abscesses of the lungs.

Two echinococcus cysts of lungs, one following a suppurating echinococcus cyst of the liver.

An abscess of the lung following bronchopneumonia.

A case of gangrene of the lower lobe of the right lung.

The various operations performed and the after-treatment are given in great detail.

6. Heinemann describes in detail a method of obtaining and maintaining extension of fractures of various kinds by the use of nails. A metal disk is placed at both ends of the nail to aid in the maintaining of the extension. A number of cases are reported. The article is well illustrated and the conclusions which the author draws are as follows:

(1) Extension by the use of nails is a useful modification in the extension treatment of fractures.

(2) The use of this method aids wonderfully in obtaining union.

(3) Indications for its use are:

*a*. Old ununited fractures with great deformity.

*b*. Compound fractures with extensive lacerations of the soft parts.

*c*. Recent fractures with great displacement.

*d*. Corrective bone operations where there is extensive retraction of the soft parts. [J. B. S., JR.]

## Obituaries.

### ALOYSIUS O. J. KELLY, M.D.

DR. A. O. J. KELLY died from the effects of diabetes in Philadelphia, Feb. 23, at the age of forty. Born in Philadelphia in 1870, he was graduated from La Salle College in 1888, receiving a Master's degree from the same institution in 1891, the same year that he attained his doctor's degree at the University of Pennsylvania. After graduation his appointments and work may be summarized as follows: Resident physician, St. Agnes Hospital, 1891–92; post-graduate student abroad, 1892–94; assistant in medical dispensary in the University Hospital in 1894, and thereafter successively instructor in physical diagnosis, instructor in clinical medicine, associate in medicine, assistant physician to the University of Pennsylvania Hospital and assistant professor of medicine. From 1900 he had also been professor of the theory and practice of medicine in the University of Vermont. Other appointments were professor of pathology, Women's Medical College, 1906; pathologist to German Hospital, 1897; physician to St. Agnes Hospital, 1897; physician to St. Mary's Hospital, 1895–1902; director of laboratories in Philadelphia Polyclinic, 1895–97. He was also for four years editor of the *International Clinics*, and for three years, since 1907, had been editor of the *American Journal of Medical Sciences*. He was a member of the Association of American Physicians and of many other learned societies, and was a frequent and illuminating contributor to medical progress, not only through his editorial activities, but also as an original investigator. He had completed at the time of his death a textbook on Practice and was engaged, in collaboration with Prof. John H. Musser, in the editing of a work on Treatment, in three volumes. He was also the author of the article on Diseases of the Liver in Osler's "Modern Medicine."

In his death the profession loses one of its most active and promising men at a period of life when much might have been expected from him in the immediate future. We quote a part of the minute adopted at a meeting of the Faculty of the University of Pennsylvania Medical School regarding his life and work:

"Serene amidst all difficulties, judicious under every circumstance, generous and winsome, able and brilliant, gifted with clearness of diction and aptness of explanation as an instructor, indefatigable and interested in the practice and study of his profession, A. O. J. Kelly won his way in this and other institutions and in the American medical profession by sheer worth, which he manifested in always increasing degree until his death. His memory as a teacher is treasured by his students, his ability as a scientist is sustained by his recorded work; his eminence as a practitioner is witnessed by the cordial respect with which his confrères universally regarded him, and his integrity as a man and his gentle, generous character as a friend ineffaceably registered in the sorrow with which this minute is made by his colleagues."

### WALTER REMSEN BRINCKERHOFF, M.D.

DR. WALTER REMSEN BRINCKERHOFF, who died in Boston of pneumonia on March 2, was born on July 4, 1874, at Matteawan, N. Y. He received the degree of S.B. from Harvard in 1897, and that of M.D. in 1901. He served as interne and as assistant in pathology at the Boston City Hospital, and in 1902 was appointed assistant in pathology at the Harvard Medical School. In 1904 he held a fellowship in the Rockefeller Institute for Medical Research, and in 1905 was physician to the Carnegie archeological expedition to Transcaspia. In 1906 he became first director of the leprosy investigation station of the United States Public Health and Marine-Hospital Service at Hawaii, and for four years conducted at Honolulu, and in the leper colony on the island of Molokai, pathologic and clinical research which made him known as an authority on that disease. In the fall of 1910, he resigned his position at Hawaii and returned to Boston to accept an appointment as assistant professor of pathology at the Harvard Medical School, where he began with characteristic enthusiasm new work of administration, teaching and investigation. He died, like a good physician,

at his post, having attended to his duties on Feb. 28 until taken sick in his laboratory. He was a man of executive ability, a good teacher, a thorough investigator, a scientist of achievement and distinguished promise, a courteous and lovable gentleman. Personal sorrow and misfortunes had only added sweetness and strength to his character. His death is a genuine loss to his school, to the profession, and to the cause of scientific medicine. He is survived by his mother, by two brothers, and by an infant son.

### JAKOB HEINRICH VAN'T HOFF, M.D., LL.D.

Prof. Jakob Heinrich van't Hoff, who died last week in Berlin, was born at Rotterdam in 1852. He first studied technical engineering at the Polytechnic Institute at Delft, from which he graduated in 1871; and subsequently went to the University of Utrecht, from which in 1874 he received the degree of Ph.Nat.D. For many years he was professor of chemistry, mineralogy and geology at Amsterdam University, where his researches and publications in the field of physical chemistry, particularly his contributions to the theory of atomic structure, established his reputation as one of the world's foremost authorities in his special subject. In 1901 he was awarded the Nobel Prize for scientific investigation, and became professor of physical chemistry at the University of Berlin. During the same year he received the honorary degree of M.D. from the University of Greifswald, and the honorary degree of LL.D. from the University of Chicago and from Harvard College. In conferring the Harvard degree, President Eliot described him as "a Hollander translated to Berlin, the greatest living physical chemist." He was a member of many foreign learned and scientific societies.

## Miscellany.

### MASSACHUSETTS MEDICAL SOCIETY.

Annual Meeting, 1911. Preliminary Announcement of the Committee of Arrangements.

The annual meeting this year comes on June 14 and 15 and certain radical changes over the meetings as previously held are contemplated.

It would seem that the meetings of the sections on Tuesday afternoon, only two hours each, are short considering the importance of Massachusetts as a medical center. This year, therefore, there will be two meetings of each section on Tuesday, — a morning session at 10 and an afternoon session at 2.30. The section on tuberculosis will be held also on Tuesday afternoon. One of the sessions of the medical section will be devoted to a symposium on syphilis and its modern treatment. The papers of the surgical section and the morning session of the medical section cannot be announced at present, but will be of interest to the general practitioner.

The Councillors' meeting will be held at 12 noon on Tuesday, instead of 5 P.M., and the Cotting lunch served as usual.

The section meetings and the meeting of the council will be held at the Harvard Medical School, on Longwood Avenue, where the accommodations as regards hall, lanterns, etc., are exceptionally good. The school buildings and laboratories will be open to the Society, and special scientific exhibits or exhibits illustrating the papers of interest to members will be given in the laboratories. A provisional list of the laboratories or departments that will exhibit, subject to revision and change, is as follows:

Department of the Theory and Practice of Medicine, Department of Hygiene and Preventive Medicine, Department of Pathology, Department of Physiology, Department of Bacteriology, Department of Anatomy, Department of Histology, Department of Surgery, Department of Physiological Chemistry, Cancer Commission of Harvard University.

The Shattuck Lecture and reception will be held as usual on Tuesday evening at the Medical Library. The annual meeting on Wednesday and the discourse will be at the Medical School, after which the members will take cars to the Symphony Hall where the dinner will be served.

Arrangements have been made to hold the annual baseball game, which was instituted last year, between teams from the different District Societies. The society will, therefore, adjourn to the Country Club immediately after the dinner. The cup presented last year is now held by the Middlesex South District Society.

It is hoped that the morning section meetings will be well attended and the movement to make the annual meeting of more importance medically be given support. The quadrangle at the Medical School is large, fitted with benches and will make an ideal meeting place. There is no meeting hall in the Symphony Hall building except that in which the dinner will be served.

Channing C. Simmons, M.D.,
*Chairman Committee of Arrangements.*

### A LAY ESTIMATE OF THE DOCTOR.

Though it is unbecoming to speak one's own praise, it is sometimes not unpleasant to hear it spoken by others. Perhaps we may, therefore, be pardoned for reprinting the following portions of a recent editorial in one of our daily papers. Some of its compliments are undeserved, but some of its epigrammatic observations are good and may be consoling to those of us who, in the inevitable isolation from the rest of mankind which the experience of our profession involves, are sometimes prone to fancy that we are not appreciated:

"The doctor is altogether a special kind of person. His illusions are few. His inside information is enormous, and if, now and then,

he wears a superior smile, forgive him. He has probably just heard some remark which he knows to be fatuous or hypocritical. Again, his jokes are likely to be a bit technical, and his view of life materialistic. But if he has a brand of idealism, you can put your trust in it, for he has learned it in a hard school, and it is genuine. He has faced the worst, and can still believe the best. And if he has a religion, it will be worth coming at, for he has wrested it out of the actual battles of good and evil in our common life seen at close range.

"The lawyer we take into our confidence when we get good and ready; the clergyman we admit to parlor and dining-room; but the doctor goes into bedroom unannounced. He goes in at a time when the house, temporal and spiritual, has not been set to rights for his reception, but if what he sees there surprises him, he seldom lets it be known. In the healing of bodies he has opportunities for healing souls which could never come to a priest, and with which many a priest could not deal. He is the lay father-confessor, regardless of creed. In cities, his clubability is famous. He always fits. And clubs are justly full of him. Any club member is always safe in replying to any other's salutation, "Good evening, doctor." He is a safe man on committees; he can turn his hand to any public business, and, if left alone, discharge it creditably. He knows more psychology in five minutes than the philosopher in a week, and he is withal the least emotional of men. The peculiar thing about him is that while fighting his grim and silent battle with death without the applause of a crowd, often without pay, and sometimes without even gratitude, he seems superior to all these considerations. He is responding to a higher sort of *noblesse oblige* which is almost unintelligible to the average man, hot for the average prizes. Compared with the impetuosity of military men, the ecstasies of religious leaders, and the silent fortitude of starving artists, the frozen enthusiasm of the doctor is a very curious manifestation. It may be something in the training he gets, for, no matter what the youngster may have been, if he has anything in him it will go hard if his practice as a physician does not bring it out. And to him belongs the final reward of service, which is the increased opportunity for service."

## Correspondence.

### PARIS LETTER.

#### A FEW NOTES ON ALTITUDE CLIMATES.

*[From Our Special Correspondent.]*

PARIS, Feb. 14, 1911.

*Mr. Editor*: I have unfortunately had occasion recently to apply to my own case the ancient maxim "physician, heal thyself." That foul fiend the grippe laid me low with bronchial catarrh, and when the acute phase of the attack was past, the problem that presented itself was in what manner the wreckage could be put together and got into working order again with the briefest possible delay.

I knew that in such a detestable winter climate as Paris, with its perpetual gloom and dampness, there was not much prospect of shaking the consequences of this illness off before the advent of better weather in the spring, three months hence, which seemed a long time; so I decided to try high altitude, and took myself off to Switzerland.

I have spent many summers in Switzerland, but never since I was a lad have I been there in the winter. This experience, then, had all the charm of novelty; for Switzerland in winter is so different a proposition from Switzerland in summer that it might quite well be looked on as a new country.

In order to make clear what I shall have to say about the contrast between the winter climate of a Swiss altitude resort and Paris, it will be desirable first to make a few remarks about the meteorology of the latter. In doing so I shall strain every nerve to avoid showing animus, though this will be difficult. Twenty-six winters have I passed in this climate, and my feelings on the subject are deep; nothing but a glass *stilus*, vitriol as ink, and asbestos for paper would answer, were I to wax candid on this topic.

I think that people in general do not realize the comparative latitudes of Paris and New York, but come over here expecting to find rather a milder climate than at home. When, then, they run up against the weather article in which we deal between Nov. 1 and the end of March, their aggrieved tones are not without a comical side. Paris if transported to our eastern seaboard would fall on the northern limit of Newfoundland, or just at the mouth of the St. Lawrence, while New York if similarly brought to Europe would correspond about to Madrid or Naples! It is consequently not surprising that our climate should be a trying one, and in particular that the winters should seem long and dark.

We are so far north, here, that in midwinter in a broad open thoroughfare like the Avenue du Bois, the noon sun, on the rare occasions when we do see it, appears like a pale-red disk just over the tops of the houses. It is no exaggeration to say, again, that there are spells when for three, four and even five consecutive weeks the sun is not visible at all.

Paris lies in a basin, surrounded by low hills, back of which comes a wide belt of forests, through which pass several rivers. The dampness of the air, which, next to the absence of sun, is the great characteristic of this climate in winter, is consequently intense. A good deal of the time it approaches saturation point, and just as soon as the light wanes, at three or four o'clock, it precipitates, comes down in insensible rain, and wets everything until next day. This dampness seems to hang over the city like a blanket for weeks at a time, shutting out the light, and keeping us wet and chilled to the bone. The chilliness it engenders is something awful; at + 5° C. the cold is far more penetrating in Paris than at − 10° C. in the mountains, of which more anon.

The final feature in our climate here is the rank dust. The low-bodied motors fly along and churn up the irritating dirt coming from the tarred pavements, which, in addition, whenever the thermometer approaches the freezing point, are not watered by order of the authorities. So you will realize the outlook in winter in this city for a patient with a good attack of bronchial catarrh! Now for the other side of the picture.

The cars brought me to Lake Geneva, and then I took a little electric train that zigzagged manfully up a steep grade. Everything was misty there, too; that end of the lake is notorious for its winter fogs, and my first impression was that it had hardly been worth while leaving a Paris fog for a Swiss one. But this conclusion was premature, for by the time we had risen to 2,500 feet the clouds lay spread out over the lake below us like billows of cotton, and at 3,000 we were in an entirely different universe, a region of bright sunshine, deep blue skies, rocks, pines and a heavy layer of snow. Not only was the physical world changed, but the population as well; for at each station the train was boarded by bands of young people of both sexes, dressed in white sweaters and knitted caps, and carrying skates, skis, sleds, etc., all bound to a sporting center, brown, freckled, hardy-looking and having the time of their lives. You have probably heard that during the past few years all of the high resorts of

Switzerland have opened up in winter for a season of mountain sports from December to March, and that this idea has proved a perfect gold mine. It can furthermore be remarked, in parenthesis, — for the benefit of those who do not find the pleasure they derive in travel heightened by running across herds of German trippers, — that, so far at least, they do not seem to have taken to these winter sports to any extent; while the English, who formerly used to frequent Switzerland in summer but had been purely and simply driven away from it by the ever-increasing invasion of the Germans, have now come back to it again in winter and form the main element at these resorts.

I left all these delightful young people at the center they had been making for, where I devoutly hope they had the ripping frolic that they were manifestly out after, and continued on in the little train for some distance farther. Where I went I shall not say; there are some good things it is well to keep for home consumption. Let it suffice that up among the Vaudois Alps there is an interesting old chalet, now a quiet little inn, but formerly the homestead of one of the local families of importance. It has been there since 1750; its hospitable arms opened and took me in, and I was graciously greeted by the little band of choice spirits stopping there, — also people who know a good thing when they have found it, and don't go around talking about it. However, here is a photograph of the chalet, just to make your mouths water!

The altitude was about 3,000, deep snow covered all the environs, the air was stingingly cold and crisp, and the pines added the proper tone to the landscape and, incidentally, held the snow to the mountainsides and prevented it from slipping down on to our heads. To breathe that air was simply a benediction, and I felt better inside of an hour. So long as the sun remained visible we were as comfortable as you please; but as soon as it disappeared, things began to happen. I who was new at this game was simply appalled to see the rate at which the mercury fell. Each time I took a turn to the front door it had dropped a couple of degrees Centigrade, and I fully expected it at that pace to finally sink into the bulb and dry up on the bottom. This speed, however, naturally did not continue; still, by bedtime the thermometer stood at — 10° C., and when I arose the next morning it marked — 16° C., a temperature I have never seen since I left America.

From that time on I devoted my energies to getting my damaged mucous membranes into shape again. But really, it was too dead easy, in such an air as that. I observed very soon that my cough consisted of two distinct elements — the irritative and the mechanical; the former had evidently been kept going in the lowlands by the damp, dust, smoke, germs, etc., for it ceased altogether in the mountains inside of a day or two, leaving nothing but the mechanical side of the question. Whenever mucus began to obstruct a tube, along came the cough-broom and swept it out, and that was the end of the matter. No mucus, no cough. This was a very evident gain, for with the disappearance of the everlasting, ineffective, irritative cough there naturally ensued much less bronchial congestion and consequently less mucous secretion.

Another great feature of this altitude climate was its remarkable dryness. Thus a sponge hung out of the window up there would dry in a short space of time, whereas in Paris you might hang it out by the week without result. Dampness alone, without dust or germs, irritates a mucous membrane, and in addition it naturally impedes pulmonary evaporation, an important factor in troubles of the respiratory tract.

As for germs, dust, smoke and other city abominations, with this thick mantle of snow they were, of course, totally absent. Up there it was perfectly feasible, even at the start, with bronchial tubes still inflamed, and in spite of the intense and to me altogether unaccustomed cold, to take a full breath down to the farthest thoracic limit without the slightest inclination to cough; on the contrary, it seemed positively soothing to the bronchial tract. The more of this air that penetrated, the better it felt.

I noticed another peculiarity up there that I confess I did not altogether understand, as in it I was in total opposition to the rest of the visitors. We had a cold and a warm side of our valley; into the former the sun *never* penetrates during winter, as it is shut out by a range of hills, while on the latter the sun shone between 9.30 and 4 P.M. Now the rest of the people stuck to the sunny side of the valley, and could not be tempted away; but I used to go down to the stream, cross the picturesque old stone arch thrown over it, and make for the road in the shade where the natives were hard at work getting out logs and hauling them on runners to the station. The climate over there seemed to key me up to concert-pitch, and the bitter snapping cold evidently discouraged my germs to such a degree that they finally gave the affair up. For cold it was over there, and no mistake, something deadly. The horses would come jingling along, their harness covered with bells, and looking more like hugh white porcupines than anything else. They had their winter coats, of course, and the aqueous vapor from their breath, as they puffed over the weight of the logs, congealed instantly on the nearest hairs, until all their front portions were frosted white, the result being most peculiar.

I never grew tired of walking on that log road. This was real winter, as I had not seen it since my boyhood. The snow scrunched beneath my heels, my ears became numb, I had to trot to keep the circulation going, but the colder it was, the finer I felt. There was, a few kilometers below our place, a point where the valley contracted, and the stream ran through a deep gorge, the road being carried along among the pines high up on one side. This was the coldest place of all, and I delighted in it, only I had to keep on a brisk move to remain alive. The snow there was so dry as to be almost like powder.

I noticed a discussion in a paper the other day as to whether there is such a thing as a dry fog. We have, in Paris, mists of all degrees, from those that *seem* dry, and in which the sidewalks are not even moist, to those in which the trees and walls simply flow with water and the streets are filled with mud. But up in these Alps I saw what the Scandinavians call a "frost-mist," a very beautiful sight. For a day our weather was milder, and then one night down went the mercury again head over heels, and during the next forenoon the valley was filled with a typical frost-mist, white above and purplish-black beneath. As the cold was intense such a mist can only be composed of minute atoms of ice; but as a matter of course an ordinary fog always consists of moisture, the seeming dryness of some, which is very real, being due to the relative slight degree of saturation. I found that the frost-mist did not irritate the air-passages at all.

A further element that makes such cold quite tolerable is the total absence of wind, which I am informed is characteristic of these high Alpine valleys in winter; of this St. Morits is a striking instance. The one great drawback

to that place in summer is the furious winds and dust; but in winter it is as still as indoors.

The remark may be made that my treatment of bronchial catarrh is a novel and startling one! All I can reply is that it succeeded, and that by the end of a week I was transformed. It goes without saying that the bracing climate acted as an energetic stimulant to the general condition, and that I ate and exercised as I haven't for years. As for sleeping, the village was simply a grave at night — not the slightest sound, not a rooster, not even a clock for the hours. "S."

## ANTISEPTIC INHALATIONS IN PULMONARY TUBERCULOSIS.

NEW YORK, March 3, 1911.

*Mr. Editor:* May I ask you to give space to the following letter just received from Dr. F. Morris Class, physician in charge of tuberculosis work at the Vanderbilt Clinic in this city, which it seems to me speaks for itself.

I could duplicate or triplicate it readily.

Dr. Class writes:

"I am using zinc perforators with creosote in practically every case under my care in Vanderbilt Clinic in whom medication for excessive cough, etc., seems necessary. I vary it sometimes with periods in which I prescribe a formalin combination, as some tire of the continuous odor of the creosote. I almost never give a depressant mixture by mouth; I never give a nauseant. I use straight morphine in the vicious terminal stages.

"At any time, should you care to visit the Day Camp on the roof of Vanderbilt Clinic, you will see a more or less large number of the zinc inhalers in use.

"In a recent article that I have just written, I have taken the liberty of quoting you in regard to inhalers. The article is called 'The Treatment of Cough in the Consumptive.'"

Very truly yours,
BEVERLEY ROBINSON, M.D.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, FEB. 25, 1911.

| CITIES. | Reported deaths in each. | Deaths under five years. | CITIES. | Reported deaths in each. | Deaths under five years. |

## SOCIETY NOTICES.

NEW ENGLAND HOSPITAL MEDICAL SOCIETY. — There will be a meeting of the New England Hospital Medical Society, at Kensington Building, Boylston Street, Thursday, March 16, at 7.30 P.M. The subject for the evening is "Social Service Work," and talks will be given by Dr. Jeffrey R. Brackett and Miss Ida Cannon. Light refreshments after the meeting and all are cordially invited.

MARGARET L. NOYES, M.D.,
*Secretary.*

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A meeting of the society will be held in John Ware Hall, Medical Library Building, on Monday, March 20, 1911, at 8.15 P.M. Addresses: "The History of the Royal College of Physicians of London," Dr. Thomas McCrae. "Some Medical Gossip Pertaining to the Last Illness of Queen Anne of England," Dr. Charles G. Cumston. "Science at the Medieval Universities," Dr. James J. Walsh. Members of the Suffolk District Medical Society are cordially invited to attend.

ROBERT M. GREEN, M.D., *Secretary,*
78 Marlborough Street.

BOSTON MEDICAL LIBRARY IN CONJUNCTION WITH THE SUFFOLK DISTRICT MEDICAL SOCIETY. — Medical Section Meeting, John Ware Hall, Wednesday, March 15, 1911, at 8.15 P.M. "Some of the Effects of Intense Heat other than Heat Stroke and Heat Prostration," By David L. Edsall, M.D., Philadelphia. Discussion. Light refreshments after the meeting.

EDWIN A. LOCKE, M.D., *Secretary,* 311 Beacon St.
HENRY JACKSON, M.D., *Chairman,* 380 Marlborough St.

## RECENT DEATHS.

DR. DANIEL MAYNARD BURGESS, retired, died at his home in New York on Feb. 28. He was born at Richfield, N. Y., on Dec. 21, 1828, and was graduated from the medical department of the University of the City of New York in 1855. While an interne at Bellevue Hospital he did excellent work during an epidemic of cholera, and later he studied for some time abroad. For thirty-two years Dr. Burgess was health inspector for the United States government at Havana, where he became widely known as an expert on yellow fever. He remained in this position until the outbreak of the Spanish-American War.

DR. DANIEL A. CURRY, of Englewood, N. J., died on Feb. 28, at the age of seventy years. He was graduated from the medical department of the University of Buffalo in 1869, and had practiced for thirty years at Englewood, of which city he was the first mayor. During the Spanish-American War he served as surgeon of the Fifth New Jersey Regiment.

### THE LUMBO-SACRAL ARTICULATION. AN EXPLANATION OF MANY CASES OF "LUMBAGO," "SCIATICA" AND PARAPLEGIA.

BY JOEL E. GOLDTHWAIT, M.D., BOSTON.

An experience of the writer within the past year in connection with the treatment of a patient with a spinal lesion was so disastrous to the patient and so distressing to the writer that a series of investigations were started in the hope of bringing some relief to the patient and at the same time of preventing such happenings in the future. It is this study which represents the basis of this communication, and in order that it may be fully understood the case that led to it is first reported.

The patient was a man thirty-nine years of age, with nothing in his family history or previous history of importance, except an attack of hypertrophic arthritis (osteo-arthritis) of the lumbar spine seven years previous for which it was necessary for him to wear a support for several months. From this he entirely recovered and had up to the time of the accident led a very active life, both physically and mentally.

In January, 1910, when very tired from a long stress of work, in lifting a heavy object he strained his back, producing a distinct displacement of the sacro-iliac joint upon the right side. The condition was recognized at once, and under nitrous oxide anesthesia the bones were replaced without difficulty, there being a perfectly definite slip as the replacement occurred. This was followed by a fairly normal recovery, so that in about three months the subjective symptoms had largely disappeared.

At that time, after a fairly long car journey, he carried a very heavy suit case in one hand, without change, for a distance of over half a mile, with the result that the back became painful, so that two days later he was seen by the writer because of pain and sensitiveness in the lower back. At that time the sacro-iliac joints were shown to be strained, but the bones were not displaced.

The next night, in turning over in bed, he felt a distinct slip exactly similar in all its sensations to that felt at the time of the first displacement.

In the morning, after having a restless night, he was able to get up and take his usual tub bath. On trying to get out of the tub, in leaning forward and straining to get up, something slipped in his back, entirely different from anything he had before experienced. The body was drawn forward and to the left; there was intense pain so that it was with great difficulty that he was able to get back to his room, and the suffering continued until he was seen by the writer four hours later. At that time the body was held bent forward and to the left. There was extreme tenderness in the sacral region, with pain extending into the legs, the right being much worse than the left.

Supposing that the condition represented a sacro-iliac displacement with the extreme lateral deformity which is sometimes seen, under light ether anesthesia the sacro-iliac joint was manipulated and slipped into place, a perfectly definite slip developing with the replacement. From this the expected relief did not come, the body was still drawn forward and to the left, and the severe pain continued. Supposing that the continuance of the symptoms was due to an imperfect replacement of the bone, or that the difficulty was still in the sacro-iliac joint, an attempt was made later in the day to hyperextend the spine to more perfectly effect the reposition and at the same time to apply a plaster of Paris jacket for fixation. The patient was raised by the writer and his assistant, no anesthetic being used, and placed upon the back on the frame used for such purposes. As he was placed in position there was a moment of intense pain followed by complete relaxation, a condition which has been seen by the writer several times when a displacement of the sacro-iliac joint has been present and has been corrected in this way. Supposing that this was what the relaxation meant, a jacket was hurriedly applied, but in a very few moments numbness of the legs developed. Supposing that this was due to a strained position with the legs extended, a pillow was placed under the knees, but the condition increased until in a few moments there was complete loss of sensation. The jacket was hurried, the patient being on the frame in all not more than ten minutes, and as he was taken off, gas escaped from the bowel, there being a complete paralysis of the rectal and bladder sphincters, as well as complete sensory and motor paralysis of the legs. The patient was put in bed and turned over to the left side. In a few moments power and sensation began to return in the legs so that within two hours the use was normal, and for the sensory disturbance there there was left only a slight numbness in the dorsum of the right foot. During the night the patient twice rolled on to the back, and both times the paralysis returned, to disappear, only less completely than it did at the first time, when he was again turned on to the side. The next morning there was a complete paraplegia present, except that the sensation had returned to the anterior part of the thighs.

The patient was seen by numerous consultants, but in spite of their assistance he remained in practically the same condition, with paralysis of the sphincters and paralysis of both legs, both sensory and motor. There was much pain of an explosive or lancinating character referred to the legs and feet, with a particularly constant and severe pain referred to the upper part of the rectum. This point of sensitiveness could easily be reached through the rectum and was located at the upper part of the sacrum, definitely, as the condition is now understood, at the lumbo-sacral articulation.

At the end of six weeks, there having been practically no improvement, and the diagnosis still being uncertain, an operation for the exploration of the spinal canal was performed by Dr. Harvey Cushing, and the spinous processes removed from the first lumbar vertebra to the

middle of the sacral region. In this exploration nothing abnormal was found except a narrowing of the osseous canal at the lumbo-sacral junction. The cauda equina appeared normal; there was no evidence of hemorrhage, and no evidence of new growth. No immediate improvement followed the operation, but a gradual improvement has taken place since and this is still going on. Both the sensory and motor conditions have improved, the sensory having improved more rapidly than the motor, and at the present time, eight months after the accident, the patient is able to move about with canes, there still being considerable pain, especially in the rectum.

Naturally such a result led not only to great distress of mind to the surgeon, but to much speculation as to the cause of the paralysis, partly because of the prognosis to the patient and partly because the procedure which led to the paralysis must often be repeated in the treatment of spinal diseases. It was evident from the different opinions which were advanced by the different consultants that the case was unique and that the nature of the condition was not understood. It was also evident that unless the cause of the difficulty could be understood, other patients could not be protected, nor could the surgeon approach his work with any proper degree of composure.

In the attempt that has been made to explain the condition the writer is indebted to Prof. Thomas Dwight, of the Anatomical Department of the Harvard Medical School, for his assistance and his encouragement. With him the writer is also indebted to Professor Warren and Dr. David Cheever, of the same department, and to Dr. W. F. Whitney, of the Warren Museum, for assistance in obtaining material upon which the anatomical studies were made.

In the first place, in the study of the case, it was evident to the writer, and the opinion was shared by Dr. E. W. Taylor, who was in frequent consultation, that whatever happened at the time of the development of the paralysis, that the spinal cord or cauda equina could not have been torn or crushed, because after there had been complete paraplegia, when the patient was turned upon the side, the paralysis, both sensory and motor, almost wholly disappeared. This was repeated twice during the first night, as the patient rolled from the side to the back. It furthermore did not seem that the paralysis could be explained by hemorrhage, since to have developed so rapidly, a very large hemorrhage would have been necessary, and with such a hemorrhage the temporary recovery from the change of position would hardly be possible. Hemorrhage into the cord itself did not seem possible for the same reason and also because of the distribution of the paralysis. Tumor in the spinal canal or disease of the bones was eliminated by the operation.

The more it was studied, the more it seemed that some mechanical element must be the real difficulty, and that the point of pressure was probably somewhere below the giving off of the lumbo-sacral cord, although not much below this because all of the nerves making up the cauda equina below this point were involved. It was obviously spinal, since no lesion or involvement of the nerve roots or of the sacro-iliac joints could explain so complete a bilateral condition.

The more the case was studied, the more definite the lumbo-sacral articulation seemed to represent the seat of the difficulty, and this was strengthened by the fact that when the patient was placed upon his back to have the jacket applied a few days after the laminectomy there was something of the same sensation that was present when the first jacket was applied, and this was at once relieved by raising the buttocks. A similar sensation also developed when he was placed upon the back to have the x-ray taken.

## ANATOMY.

The anatomical study which was carried on in order to explain the condition is as follows.

The lumbo-sacral articulation in its main part inclines downward and forward about 30° (Fig. 1) when the person is standing erect, and except for the articular processes at the back, the spine would naturally slide forward upon the sacrum. The ligaments under normal conditions represent considerable support, but they would naturally be stretched in a short time and displacement of the bones take place except for these articular processes.

The lumbo-sacral joint is capable of considerable motion, fully one half of the motion of the trunk below the lower dorsal region being made in this articulation and the one just above it, the remainder of the motion being distributed between the rest of the lumbar spine and the sacro-iliac joints. In forward bending, since the bodies of the vertebræ are so large, the motion at the lumbo-sacral joint is made partly by the changes in the intervertebral disk, but chiefly by the articular processes of the fifth lumbar vertebra sliding upward upon the opposing processes on the sacrum. Naturally if the motion is carried too far, the articular processes will be separated and the vertebra can then slip forward upon the sacrum. If this is continued, the last lumbar vertebra may slip entirely off the vertebral articulation of the sacrum, as is shown in Figs. 2, 3 and 4, and a true dislocation or a spondylolisthesis results. In such a displacement, since the articular processes of the fifth lumbar extend below the lower surface of the body of the bone, the body of the fifth is raised so much above the superior surface of the sacrum that there is practically always a space for the cauda equina, — this, together with the fact that the change takes place slowly, making gradual readjustment possible and explaining the fact that paralysis under such conditions does not result. The relation of the bones to each other as such displacement takes place with the space for the cauda equina constantly present is shown in Figs. 5 and 6, and Figs. 7 and 8.

If, now, the displacement of the fifth lumbar or the separation of the articular processes takes

place only upon one side, a much more serious condition at once results. The displaced articulation slides forward and to the outside (Figs. 9 and 10), with the result that the whole spine with the body of the fifth lumbar vertebra is rotated forward on the side of the displacement (Figs. 9 and 11). With this rotation and with the moving forward of the displaced articular process, the other process is drawn nearer to the center of the body (Figs. 9 and 10), at the same time necessarily being drawn forward, with the result that the spinal canal is narrowed (Fig. 10), and the narrowing may be so marked that the entire cauda equina is compressed, with paralysis, either complete or partial, below this point.

Such displacements may be due to simple direct violence in which the body is bent sharply forward or to one side, but unless some of the contributing factors that are to be described are present, it is probable, since the ligamentous protection of the joint is so strong, that in such displacement the bones would be broken at such time as well as dislocated, making the condition much more hopeless.

Of the contributing factors that could favor such displacements, in the first place simple postural habits in which the back is flattened (Fig. 12) must result in making the long axis of the sacrum more nearly vertical, and consequently the lumbo-sacral articulation more nearly horizontal. In this position the interspinous ligament in the lumbo-sacral portion of the spine must be stretched. With this naturally the motions at that joint will be more free and the articular processes must be drawn more or less apart with displacement if the position is increased or if any of the following conditions are present.

### ARTICULAR PROCESSES.

If, as the result of congenital conditions, the articular processes are shorter than normal, or if the lumbo-sacral articulation has the dorsal characteristics with the articular processes facing forward (the long axis of the joint being lateral) instead of lumbar characteristics with the articulation facing laterally (the long axis being antero-posterior), then displacement of the fifth lumbar forward upon the sacrum becomes more easy.

Of these anatomical peculiarities of the articular processes there is a wide range. The variation in the length and inclination of the processes is shown in Fig. 13.

The variation in the shape of the articulations is very great, and of these variations there are two types which are so common that numerically both might be said to be normal. One of these is with the articulation sharply crescentic (Fig. 14), the lateral portion extending backward almost at a right angle with the anterior or transverse portion of the articulation, and the greater portion of the articulation upon the process of the fifth lumbar facing outward at the side of the body. Into the crescentic articulation upon each side of the sacrum the articular processes of the fifth lumbar vertebra fit, making naturally a very stable joint.

The other type consists of a flat articular surface with the axis nearly transverse (Fig. 15) so that the plane of the articulation of the process of the fifth lumbar vertebra faces forward. It is obvious that such an articulation is much less stable than the preceding type, and when it is realized that there is often considerable forward inclination instead of the usual vertical position in this articulation, together with the fact that the length of the articular processes varies, both features being suggested in Fig. 13, the instability is more apparent.

While these two types are common, and usually exist as distinct representatives of one or the other type, there are many variations from these, either type merging more or less into the other. Not only this, but in several specimens examined both types have existed in the same individual, one side showing one form and the other side the other form (Fig. 16). The effect which such peculiarities of form must have upon the motion or stability of the part must be evident. Under such conditions, in bending toward the side with the crescentic articulation there is nothing upon the opposite side to prevent the upper part of the crescentic articulation acting as a fulcrum and the joint on the other side being strained or weakened.

If, now, for any reason, such as habit of posture, the level of the top of the sacrum is changed so that one side is lower than the other, the separation of the lumbo-sacral articulations will naturally take place more easily, and most easily upon the side on which the sacrum is lower. It is probable that in displacements of the sacro-iliac joint (a condition which is almost always unilateral) such changes in the level of the top of the sacrum do take place, and it seems to the writer that the influence which this must have upon the stability and possible displacements of the lumbo-sacral joint must be constantly borne in mind in connection with these common and previously considered simple (sacro-iliac) displacements. The possibility of there being the short articular processes, or of the shape of the articulations being unlike upon the two sides, or of the transverse processes being peculiar (a condition to be described later) must be recognized and proper precautions taken to prevent unpleasant complications.

### TRANSVERSE PROCESSES.

Another factor which seems to the writer of as much if not of more importance than the conditions which have been described is the marked variation in the length and shape of the transverse processes of the fifth lumbar vertebra, and also the variation in the height of the superior aspects of the lateral portions of the sacrum.

Of the transverse processes the variations range from the short and small processes (Fig. 17), which could cause no possible interference with the lateral motions of the body, to the long and broad (Fig. 18) process, which in its extreme is fully sacralized and joined to the sacrum (Fig. 19). The effect which such a process would have

upon the lateral bending of the body is evident. If the process were fused to the sacrum there would, of course, be no motion at this point. If it were free, the impinging of the end of this process against the top of the sacrum (often forming a true joint, Fig. 20), or the posterior part of the ilium, would not only limit the motion, but if repeated would result in sensitiveness at the point of contact.

With this variation in the shape of the transverse processes the two sides are rarely the same, and this difference easily explains the difference, under such conditions, in the ability to bend to the sides. On one side the bending may be much limited, while upon the other side it may be quite free.

### SACRAL PECULIARITIES OF FORM.

Of the sacral variations, the superior surface of the lateral portions may be flat so as to be lower than the spinal articular surface, or they may be raised considerably so that they are higher than this articulation (Fig. 21), a condition which in the extreme is part of the fusion with the transverse process of the fifth lumbar, the sacralization just described. The effect of such formation upon the side bending of the body is obvious. With the flat surface the full freedom in the absence of other interference would exist, while with the raised surface the amount of the limitation would depend upon the extent of the elevation and also naturally upon the shape of the corresponding transverse processes of the vertebra just above.

The effect which such conditions must have upon the stability of the lumbo-sacral joint is probably perfectly obvious, but since this seems to the writer to be one of the most important points in the communication, elaboration seems wise.

With the small and short transverse process, or with the flat or regular sacral surface, these features naturally contribute little if any to the direct stability or the instability of the lumbo-sacral joint. If, however, the transverse processes are long or broad or the sacral surface is raised or irregular, either or both of these conditions not only limit the side bending, but in such bending the point of contact must, if force is applied, represent the fulcrum, the direct effect of which would be to pry apart the articulation of the articular processes upon the opposite side.

If with this at the time of the application of the force the body is also inclined forward, in which position the articular processes must naturally be partly separated, the stability of the joint will naturally be less and the harmful effect of such application of force be more easily produced.

As still further contributing factors to the limitation of motion in this region as well as the differences in the stability, the variations in the width of the upper part of the sacrum must also be considered. This variation is also shown in Fig. 21. With this also the shape and width of the posterior parts of the wings of the ilia vary. It is easy to see that these facts make it possible for the long transverse processes of the fifth to at times strike against the ilia in certain motions and thus represent another possible cause of pain or displacement. Still farther, the strong ilio-lumbar and the lumbo-sacral ligaments extend from the transverse processes of the fifth to the posterior and superior portions of the crest of the ilia and to the superior surface of the sacrum. Under ordinary conditions these naturally increase the stability of the lumbo-sacral joint, but if the relation of the bones is changed upon either side, as would exist when the usual unilateral sacro-iliac displacement takes place, the action of these ligaments must be changed. In the usual displacement, which is with the sacrum backward, or the ilium forward, the iliac attachment of the ilio-lumbar ligament is moved forward, with the result that it must tend to draw the transverse process forward upon that side. Since with this the backward movement of the sacrum at the top must tend to separate the articular processes, it is obvious that with the possible presence of some of the irregularities of formation which have been described, the necessary instability of the lumbo-sacral joint under such conditions must be apparent.

If with this the elevation of the two sides of the sacrum is different, as might occur if a sacro-iliac displacement existed, the ease with which displacement at the lumbo-sacral articulation in connection with the application of force as just described would naturally be greater.

### MECHANISM OF THE DEVELOPMENT OF THE PARALYSIS.

If, now, the articulation upon one side is drawn apart or separated and with this the articular process of the fifth lumbar has slipped forward, as must occur almost at once in such separation, an attempt be made to correct the necessary lateral and forward bend of the body without first correcting the position of the articular processes, the possibility of harmful results must be apparent. If the correction is attempted with the frame commonly used in the application of plaster of Paris jackets, in which the body is extended or hyperextended, the result must be that the displaced articular process of the fifth is forced more deeply into the groove in front and to the outside of the articular process upon the sacrum, and since both processes are wedge-shaped from tip to base, such crowding together must cause more rotation of the spine and must draw the articular process of the fifth of the opposite side toward the center of the body. At the same time, because of the rotation which has taken place with the bones above the sacrum, the process must be drawn somewhat forward as well as toward the center.

The effect of this upon the structures passing through the spinal canal must be apparent. The canal must be narrowed, and if the weight of the body is applied directly to the bones of the spine, as it is with the use of the frame here mentioned, with the articular processes of the

FIG. 23.

fifth no longer held back by their opposing articulations on the sacrum, this vertebra, with, of course, the spine above, must be pushed forward and the articular process that was drawn toward the center of the body is crowded still farther into the spinal canal, with compression of the cauda equina. If with this the thighs are allowed to sag backward, as is usual in the hyperextended position, the pressure upon the cauda equina will be greater.

### INTERVERTEBRAL DISK.

Another element, which was not at first appreciated, but which is undoubtedly of much importance as a direct cause of the paralysis, consists in the formation and possible displacement of the intervertebral disk, lying between the body of the vertebra and the sacrum. This structure, as is peculiar to the same structures in the rest of the spine, is made of two parts, one the peripheral or outer portion, called the "annulus fibrosus," the other the central portion, called the "nucleus pulposus." Histologically, the two parts are quite unlike, the outer part being made up of concentric layers of connective tissue fibers, and serves to assist partly in holding the vertebræ together, but probably the more important function is to hold the central or pulpous portion confined so that its shape can be preserved. The central portion is an oval mass of fibro-cartilage which exists under high pressure.[1] This is placed a little back of the center of the disk and practically represents the point upon which the weight of the body is balanced, motions of the body in bending being made upon this as a center. The pressure under which this pulpous portion exists and upon which its importance as the pivotal point in the body motion must depend is at once apparent if a sagittal section of the spine is made. In this, this "pulpous" or central portion bulges markedly, while the remaining or outer portion does not alter its position. At the same time, in such a section, the histological differences between the two portions of the disk is easily apparent.

If, now, with such a condition existing the spine is bent in any direction so far that the attachment of the outer or annular part of this cartilage is separated from the bone, the result must be that since the confining element of this central or pulpous portion is removed, it forces the detached outer portion outward and projects beyond the edge of the vertebra. If, now, this separation of the outer portion of the disk occur at the back, as might easily occur if the articular process had been separated or displaced as has been described, the result must be that the detached portion of the disk is crowded backward and must narrow the spinal canal. If the articular processes have been separated upon one side, naturally the separation of the intervertebral disk will occur chiefly upon the side of the separation or away from the side toward which the body is bent. This would naturally result in there being more paralysis or irritation of the cauda equina upon one side. The projection of the disk into the canal when the posterior part is separated is shown in Fig. 22. That which shows of the disk projecting backward in this drawing is schematic, since if the sagittal section were made the projection would naturally be toward the center, that being the direction of least resistance. To demonstrate actually the backward projection into the canal, the body of the vertebra must not be disturbed, but simply with the spinal canal exposed the attachment of the disk be loosened, in which case the projection of the disk is apparent. This can easily be demonstrated in any reasonably fresh subject, but is suggested in this manner as being more easily presented and more strikingly suggestive.

The projection of the central portion if the sagittal section of the body is made is so often seen and so easily demonstrated that illustration is not considered necessary.

Because of the structure of the disk if such separation occurred the projection of the disk and the possible paralysis would be gradual in development, since the dense annular portion must be stretched by the central portion and would require some hours or possibly days for the full extent of the displacement to develop.

In the case here presented, probably this condition, as well as the displacement of the bones, existed or was produced. The patient had been very tired, so that he drooped the body as one does at such times, with strain and weakening of the posterior spinal ligaments. When in this condition in lifting, the sacro-iliac joint was slipped, this naturally leading to a temporary still greater weakening of the ligaments. This was followed, before he was fully well, and when the body was still used drooped, and with the back flat, by the strain in carrying the heavy suit case as a one-sided load. In this weakened condition, in turning over in bed, the sacro-iliac joint was again displaced. With this displacement present, so that the muscles of the back could not work naturally for protection, and with the two sides of the sacrum changed as well as the relations of the crests of the ilia to the transverse process also changed, the body was drawn forward in trying to get out of the tub, with the result that the articular processes upon the side of the displaced sacro-iliac joint were drawn apart and the body was held drawn forward and to the left by the tip of the process of the fifth which had slipped forward over the opposing process of the sacrum. This naturally led to the separation of the intervertebral disk, as has been described, and to strain or irritation of the nerves in this region, both inside and outside of the canal, explaining his great pain. The replacement of the bones at the sacro-iliac joint gave little if any relief because this was not the chief trouble. In placing the patient upon the frame the back of the body was straightened, but at the same time

[1] Spaltehols: "Hand Atlas of Human Anatomy," second edition, vol. i, p. 157. "The nucleus pulposus consists essentially of a very soft mass of fibro-cartilage with irregular connective tissue bands and contains the remains of the embryonic corda dorsalis; it is separated but not sharply from its surroundings and lies nearer the posterior circumference of the intervertebral disk (see Fig. 210). In the uninjured spinal column its constituents are under high pressure so that on cutting through the disk they project markedly."

the already displaced articular process was still farther displaced, while the other process was drawn away from its normal position toward the center of the body and crowded against the cauda equina, causing the paralysis. The temporary relief by changing the position to the left side (this side was used simply because it was more comfortable than the other) is at once apparent, as is also the intense "rectal" pain which was located directly at the lumbo-sacral articulation, and any strain for voiding the urine or moving the bowels naturally not only aggravated the pain by causing motion of the spine, but because with the attachment of the rectum at the side of the spine at this very articulation, the strained and damaged anterior ligaments were irritated. The effect of such displacement at the back upon the anterior part of the spine is well shown in Fig. 23, and easily explains the anterior or rectal pain.

The fact that the pain was increased whenever the patient was put upon the back with the legs straight is also understandable, the same explanation holding for the sensations which developed when the x-ray was taken and also when the jacket was applied after the operation. It also explains the relief of this sensation instantly obtained by raising the buttocks. In such position not only would the articular process be forced more firmly into the canal, but naturally anything which tends to hyperextend the body must compress the posterior portion of the intervertebral disk, with the result that the movable or unattached portion would be crowded outward still farther into the canal. This would naturally be corrected by flexing the body slightly so that the space at the back of the vertebra would be increased, and into this the disk would naturally retract.

The fact that the pain was not relieved by the operation is also understandable, because at this time the vertebra was not replaced nor was the probably displaced intervertebral disk confined; and while it is probable that with the increased space given for the cauda equina in removing the spinous process, sufficient room has been given so that the ultimate adjustment of the parts to their natural function will take place, the immediate relief under such circumstances could hardly be expected.

It is also evident in studying the x-ray (Fig. 11) that the original displacement, both of the sacro-iliac joint and of the spine, was made possible not only by the weakened ligaments, but also by the fact that the transverse processes of the fifth lumbar were much longer than normal, so that in bending to the side they might easily furnish the fulcrum by which the weakened joints could be pried apart when the right amount of force was applied.

Recognizing all of these features, the great weakness which was present at the junction of the hips to the body with the patient when he first tried to get up is not surprising, nor is it to be wondered at that with such a condition of imperfect relation of the bones that much use of the body brings back the old pain in the rectum and the legs.

That such anatomical conditions may exist, there can be no question, since the facts here stated can easily be verified by the study of the anatomical material which is available in any well-equipped medical school or in any museum of anatomy. This being the case, and since such conditions in varying phases are by no means rare, the symptoms which result from such conditions become of much importance, partly from the point of simple diagnosis, but quite as much for the prevention of such disasters as occurred in the case here reported.

That actual paraplegia ensuing from such cases is probably not as rare as would at first be supposed is shown by the fact that during the preparation of this paper the writer has seen a patient in frequent consultation with Dr. A. H. Crosbie, in which paraplegia existed, due, not to actual displacement of the bones, as was demonstrated by operation, but in which the intervertebral disk undoubtedly caused the compression of the cord. In this case the compression should have been chiefly upon the right side; and the patient, by change of position or manipulation, could be given a paralysis of the right leg or both legs, depending upon the degree of compression of the posterior part of the intervertebral disk. This case will undoubtedly be reported fully later by Dr. Crosbie, but is here mentioned to show that probably such cases are not as rare as the first case suggested, and the writer cannot help wondering if some of the cases of so-called transverse myelitis or cases of paraplegia without bone or neoplastic disease are not due to these features.

From that which has been shown of the anatomical types and variations it is evident that the symptoms will depend upon the special anatomical features present in the special case, but with the knowledge of these anatomical peculiarities it ought not to be difficult in any case to form a fairly correct opinion of the nature of the difficulty even without the x-ray. This latter aid is, of course, very great in such cases, but it should be used only after a careful clinical study of the case has been made and a rational explanation of the symptoms reached. The x-ray should, in other words, be used for confirmatory evidence or for showing the degree or extent of any special feature that may be present, such as how long or how wide a transverse process may be, the fact that it is peculiar in its formation having been determined before the x-ray was taken. Unless this is done, the emphasis may be put upon some anatomical peculiarity which undoubtedly exists, but which is of no particular importance in the given case.

Of the special symptoms, it is obvious that with paralysis present, as was present in this case, coming on suddenly after such treatment, in the light of our present knowledge there can be little question as to the nature of the trouble. The only questions would be of treatment, and it seems to the writer that where the

displacement has occurred, operation for the purpose of cutting down on to the displaced bones and replacing them is the only safe procedure. Since the cord is already compressed, any manipulation without open incision would involve so much risk of permanently damaging the cord that it should not be attempted. At such time, because of the probable separation of the intervertebral disk and its projection into the spinal canal, the spinous process of the fifth, to increase the space in the canal, should be removed.

If the cord has not been compressed, but if the articular process upon one side has become separated with the resulting forward and lateral list of the body, it seems perfectly safe to attempt to correct such a condition by manipulation alone. In such cases, the displaced process has probably only just caught upon the top of the process below, and as yet the articulation upon the other side has not been seriously strained. In such a case, with the present anatomical knowledge, it would seem reasonable to passively still farther flex the body and throw the body farther to the side of the list to free the tip of the process, and when this is accomplished to rotate the body backward upon the side of the existing displacement. In certain cases this will undoubtedly be possible. In others it will fail, and not only fail, but very possibly at times the cauda equina may be pressed in the manipulation so that paralysis develops. Under such conditions, the operation naturally should be performed, and with the present knowledge the early relief of the nerve pressure ought to result in but little permanent harm.

The symptoms which make such a unilateral displacement plain, aside from the peculiar deformity, would be the sudden character of the onset, the great pain referred to the legs as well as the back, the tenderness directly referred to this articulation, the marked spasm of all the trunk muscles, with much less of the thigh muscles except the psoas (this is of importance in differentiating the condition from a sacro-iliac displacement, in which the spasm of the thigh muscles, especially the hamstrings, is relatively greater than the spasm of the trunk muscles), and with this the fact that the symptoms are so much increased by recumbency upon the back, the position of greatest ease being upon the side away from the displacement.

If the displacement is upon both sides, the spondylolisthesis, it may, of course, be traumatic, in which case the history with the resulting deformity ought to leave no question as to its nature, but the usual form of these bilateral displacements is of gradual development and without marked symptoms. Sensations of weakness with mild pains are the chief complaint, with the consciousness that gradually the poise or carriage of the body is changed. In such cases the sacrum is always more vertical (Figs. 3 and 4) when the person stands, and in the early stages the lumbar spine is also flat. As the fifth lumbar slides forward, the shape of the lumbar spine changes, until in the extreme it is as shown in Figs. 3 and 4. Such a condition is so gradual, and the adjustment to the condition becomes so complete, that the degree of the disability is much less than would be expected. The patient pictured in Figs. 3 and 4 was seen by the writer after the deformity had developed; and with a small belt about the hips and lower part of the body he is able with but slight inconvenience to carry on his work as a gardener.

If the patients are seen in the early stages of either the bilateral or the unilateral displacement, naturally attempts should be made to correct the condition by means of apparatus or by operation. With a large number of persons, fortunately, actual displacement of the bones has not taken place when they present themselves for treatment but the symptoms are due either to strain or weakness of the structures of the lumbo-sacral joint or to interference with the use of the part resulting from the peculiar shaped transverse processes.

If the condition is purely of joint weakness, the symptoms and treatment naturally depend upon the cause and duration. If the condition is due to a definite strain, with the common sensation of a sudden "crick in the back" (a symptom which is also common with the sacro-iliac displacements), there will be low lumbar pain, at times of much severity, and often called lumbago. The local tenderness over the lumbo-sacral joint will be definite. The spinal motions will be much limited in all directions, but as a point of importance in the differential diagnosis, the limitation of the hip motions will be slight, if any, in striking contrast to the marked hip limitation in case of sacro-iliac injury. The pain is referred partly to the back, but with this there is commonly pain and "peculiar sensations" referred to both legs. The bilateral character of the pain is of differential importance in the elimination of a sacro-iliac lesion.

In the mechanical treatment of this condition, if it be acute, such as would come from a strain or wrench, support of the strained part is the most important factor, and any form of support that steadies and limits the motion of the lumbo-sacral joint will be of benefit. In the severe cases a support as complete as a plaster of Paris jacket (fitted very low) may be needed, while in the mild cases a tight swathe fastened about the lower body is all that is necessary. Between these extremes will be found the desired support in the given case; but whatever is done for temporary relief, the treatment should not be discontinued until the poise of the body is such that there is the slightest possible tendency for strain of this part. It is obvious that a person standing as pictured in Fig. 12 must have a weakness of this joint and has a potential of trouble from which symptoms may at any time develop. Exercises, with possibly the temporary use of apparatus, should be given, and the treatment continued until the body is so used that the normal balance is possible with no strain to any one part. In correcting the poise in such a case it should always be remembered that the sacro-iliac joints are

oftentimes weak in such a case; in fact, the disturbance of poise may be due to this, and in planning the treatment this feature should be recognized.

In such an analysis it should be borne in mind that while in some cases the symptoms may be due to weakness or trouble purely at the lumbo-sacral joint, that at other times the symptoms are due to the pressure caused by the abnormally shaped transverse processes or in the joints which have formed at their points of contact upon the sacrum (Fig. 20). In these cases the symptoms are commonly pain, referred quite directly to the point of contact of the transverse process with the top of the sacrum or the wing of the ilia. The patient is usually able to put the finger directly upon the seat of the pain, and since the increased length or width of the process or the increased elevation of the superior surface of the sacrum is rarely the same upon the two sides, the pain is usually unilateral, being naturally felt upon the side of the greatest thickening. With this there is often pain extending into the leg upon the same side, this probably being due in some way to compression of the lumbo-sacral cord, either as it passes under the larger transverse process or because of the constriction produced by the lumbo-sacral ligament, which may be attached lower down in such conditions.

In such a case naturally the spinal motions will be limited, and the limitation should be that which one would expect with such an anatomical condition present. Forward bending should be free, because in this motion the transverse processes are separated. Backward bending should be limited, because in this the process should be crowded on to the sacrum. Side bending, if the condition is purely unilateral, should be limited if the bending is to the side of the thickening, but should be free in bending to the other side. The abrupt limitation in the motion when certain points are reached at once suggests some mechanical element, and is entirely unlike the gradual limitation with the constant muscle spasm invariably seen when the limitation is due to conditions of disease or inflammation. From these features alone a probable diagnosis should be possible, which should be confirmed by the radiograph.

In such a condition of peculiar formation of the transverse processes it should be remembered that while the purely local symptoms are as described, that a condition of this kind cannot exist in any marked degree without causing such a disturbance in the normal motion or function of the lower spine that strain of the lumbo-sacral articulation or of the sacro-iliac articulation results. In planning the treatment for such a condition naturally the direct and the indirect symptoms should be appreciated. For treatment one of the most important features is to see that the body is used fully erect. If the body has "settled down," as is suggested in Fig. 24, the articular processes are necessarily crowded together, and with this the transverse processes are brought nearer together. If the processes are broad or unduly long, it is obvious that conditions that could be accommodated when the body is erect would result in so much pressure when the body settled down as to demand treatment. That such conditions do exist, and also that they are by no means rare, is shown by the fact that in the week during the actual writing of this paper two patients were seen complaining of painful backs with considerable disability, in which a definite diagnosis of abnormal formation of the transverse process of the fifth with resulting pressure upon the sacrum was made and afterwards confirmed by radiograph. In both cases relief was at once obtained by using apparatus that made the fully erect position possible. In one, it is probable that with this and the proper physical training to make this poise permanent nothing more will be necessary. With the other, the shape of the process upon one side is such, and must result in such constant pressure upon the sacrum, a true joint apparently existing, that operation for the removal of a portion of this process will undoubtedly be necessary.

In conclusion, the writer wishes to make plain the facts that the lumbo-sacral articulation varies very greatly in its stability, depending upon peculiarities in the formation of the articular processes and of the transverse processes; that these peculiarities not only result in less than the normal strength of the joint, but may represent mechanical elements which not only produce strain and cause pain but may lead to such great instability that actual displacement of the bones may result, with at the same time the separation of the posterior portion of the intervertebral disk.

In such displacement, if the fifth lumbar slides forward upon the sacrum, spondylolisthesis, the condition is usually compensated for, and pressure upon the cauda equina or the nerve roots does not occur.

If the displacement be upon one side, the spine must be rotated and the articular process of the fifth is drawn into the spinal canal with such narrowing that paraplegia may result, or the crowding backward of the intervertebral disk alone may be so great as to cause similar paraplegia, but of more gradual development.

Weakness of the joints or the partial displacements may cause irritation of the nerves inside or outside of the canal and produce the bilateral leg pains often called sciatica.

## DIVERTICULITIS OF THE SIGMOID.

BY W. P. GRAVES, M.D., BOSTON.

ALTHOUGH the clinical and surgical significance of the acquired diverticula of the intestine has been only very recently recognized, anatomical knowledge of these processes has existed for many years. Sömmering, as far back as 1794, described a case of acquired diverticula of the small intestine. In 1845 Gross demonstrated and pictured diverticula in the large intestine. The condition was also described by Klebs, Alibert,

Schroeder, Sydney Jones, Astley Cooper and others. In 1896 Hanseman found, at autopsy of a man of eighty-five, four hundred diverticula occurring throughout the entire length of the intestine. These historic cases were all from autopsies and were regarded merely as anatomical curiosities. In the last translation of Nothnagel's Encyclopedia, published as recently as 1904, the following statement is made: "As these lesions [acquired diverticula] are chiefly of anatomic interest and have very little clinical significance, only a few general remarks will be made on this question."

The general recognition of the surgical importance of the subject may be said to date back less than five years. In 1906 Sampson and Gogornier published their case of obstruction from diverticulitis of the small intestine and called attention to the fact that acquired diverticula not only occurred more frequently than is supposed by pathologists, but that they are the unrecognized etiological factor in many inflammatory processes of the intestine, especially those occurring in the region of the sigmoid. In 1907, W. J. Mayo published five cases of diverticulitis of the sigmoid and at that time was able to collect only eighteen other authentic cases from the literature. Since then surgeons and pathologists have given closer attention to the subject, and the record of cases is rapidly increasing both in the operating room and in the laboratory.

Acquired diverticula are to be distinguished from so-called congenital diverticula, of which Meckel's diverticulum and the vermiform appendix are the most familiar examples. It was formerly supposed that the acquired variety results from an actual hernia of the mucous coat through the fibers of the muscles of the intestines, and the term "false diverticula" was applied to them by Cruveilher and Rokitansky to distinguish them from the so-called true diverticula, the name applied to the congenital form in which all the coats of the intestine are present. It has since been learned, however, that in the early stages of an acquired diverticulum all the coats are present, but that as it develops the muscle fibers become atrophied by pressure and disappear partially or completely. The terms "true" and "false" are, therefore, no longer to be used synonymously with congenital and acquired.

Acquired diverticula may appear at any point in the entire length of the intestine, though more commonly in the sigmoidal region. They are rarely if ever seen in the rectum. Their occurrence in the appendix itself has been noted by Kelynak, Ribbert, Edel, Fischer, Mertens and Kelly, and to these records is added another in this article. The diverticula are practically always multiple and range in number from two or three up to several hundred. In size, they rarely occur larger than a hazel nut, and many of them are microscopic. Frequently they are difficult to find, since externally they may be completely hidden in masses of fat, and when searched for from the inner side of the bowel their openings may be so small as to escape notice. For this reason probably many hundreds of cases have been undetected at autopsy, as is evidenced by the fact that in the autopsy records of many of the larger hospitals only an extremely small number have been noted, while in the records of several of the smaller hospitals where the condition has been more carefully searched for, the number of cases discovered is considerable. The diverticula are at first semiglobular in shape, but as they become larger and more distended they assume a more elongated form, usually with a constricted neck, a point which is of considerable importance in the matter of later pathological changes. Most of the diverticula of the large intestine contain feces which are retained on account of the constricted nature of the neck. The diverticula of the small intestine, on the other hand, are for the most part empty, due partly to the more fluid nature of the intestinal contents and partly to the fact that the openings are less apt to be constricted. In the small intestine the diverticula are almost invariably along the mesenteric attachment either between the leaves of the mesentery, as in Sampson's case, or just to one side, as in the case described by Klebs. In the large intestine they may occur anywhere, but more commonly they appear on some part of the free border. They are very apt to protrude into the appendices epiploicæ, and this is their commonest situation in the large intestine. Those which enter the epiploic appendages are characterized more than any others by having constricted openings. The walls of most of the more advanced specimens contain only the mucous membrane and serous coat. Some of the diverticula in the same specimen of gut may contain all the coats in their walls; others may be covered with only the longitudinal layers of muscle fibers, while others may have only the mucous and serous coats.

The etiology of these lesions has never been satisfactorily elucidated. It seems fairly evident, though not incontestably proved, that the fully developed condition is acquired and not congenital, from the fact that it has never been discovered in a child, and that it occurs in the great majority of cases after the age of fifty. The youngest case ever recorded was twenty-two (Fiedler). Klebs was the first to investigate the cause of acquired diverticula, his work being published in 1869. He studied a case where the lesions appeared only in the small intestine and found that the diverticula occurred invariably where the vessels pierced the gut, and were always closely associated with the veins. He reasoned that the presence of loose connective tissue around the vessels constitutes a *locus resisentiæ minoris* favorable to the formation of these hernial processes. This observation was confirmed by Hanseman and later by Fischer. In order to prove this, Hanseman subjected the dead gut to internal pressure and was able to produce artificial pouches which bore a certain resemblance to diverticula and in which he could demonstrate the same relation to the blood vessels as appeared in his autopsy case. He was able to accomplish this only with the gut from

elderly people. Beer repeated Hanseman's experiments but was unable to produce anything simulating pouches. Chulmsky, experimenting along the same line, found that the dead bowel, when subjected to internal pressure, always ruptured at the mesenteric border, but that the living bowel under similar pressure ruptured at the free border. Experimentation of this kind is obviously unprofitable and can prove nothing as to the real formation of these pouches. Diverticula, like practically all hernial protrusions in the body, are unquestionably the result of a slow gradual process of stretching, a condition which can in no way be compared with the result of sudden or acute force used in these experiments.

Graser, in 1898, in line with Klebs, attempted to show that the local weakening of the intestinal wall was due to an enlargement of the vessel holes into the intestine as a result of a chronic passive congestion, the case which he reported having died of chronic heart disease. He examined the intestines of a number of cases where there had been mesenteric venous stagnation and in a certain percentage of them discovered microscopic diverticula situated always at the vessel openings. These observations of Graser, Klebs and others, though sufficiently convincing as regards the diverticula which occur near the mesenteric border, do not, however, account for those which appear on the free border of the large intestine where the wall is not pierced by vessels. In the large intestine the more common situation for diverticula, as has been pointed out, is into the epiploic appendages. Bland Sutton has shown that the fat of these appendages is directly continuous with the fat of the subserosa, and, therefore, naturally constitutes a point of lessened resistance especially favorable for the extrusion of a diverticulum. A study of the clinical cases reported so far shows that the great majority have been more or less obese and that the intestine is covered with an abnormal amount of fat. This was strikingly so in Case 1 reported in this article, where the patient, though not particularly obese, exhibited an extraordinary amount of intestinal fat. Some of the reported cases have been conspicuously lean, though many had become emaciated after being fat. The presence of abnormal fat can at best only be regarded as a factor favorable to some other underlying predisposing cause. Constipation with the resultant increased intra-intestinal pressure has been generally considered to play an important rôle in the causation of diverticula. In one series of twenty-two cases reported, seventeen had constipation. This is not, however, particularly impressive, as one would expect to find a large percentage of elderly people constipated, while the comparative rarity of diverticula is out of all proportion.

Beer, in an excellent article published in 1904, points out that the underlying cause of the formation of diverticula must be a muscular deficiency in the wall of the gut. He writes, "The fact that diverticula occur in old people and people whose intestines have been more or less worked out, as is evidenced by constipation, points to a muscular deficiency, and in this muscular weakness the cause of the formation of the false diverticula must be solved." Such an explanation, somewhat vague though it is, and to a certain extent evading the question, is more satisfactory than any other. Given this constitutional local muscular deficiency, the protrusions would be most likely to occur at the points of less resistance, namely, at the vessel holes of the gut or at the attachments of the epiploic appendages. Old age and the accumulation of fat on the intestines would also be a favoring factor in connection with a constitutional local muscular deficiency. If the intra-intestinal pressure constitutes the pulsion which ultimately pushes out these diverticula, chronic constipation and habitual gas formation would naturally encourage the condition. It is to be expected, too, that the sigmoid flexure would be a particularly favorable situation for the lesions, for, being a reservoir for feces, and, excepting during defecation having a reverse peristalsis, it is here that any anatomical results from constipation would most likely be felt. In addition to this, the walls of the sigmoid are naturally inclined to sacculation and are more likely to be loaded with a covering of fat than any other portion of the bowel.

The question then arises, What is the cause of this local muscular deficiency? If, as Beer says, "it is due to a wearing out of the bowel by old age and constipation," why does it not appear more frequently, and why does it appear in fairly robust persons not greatly advanced in years and who have never suffered from constipation? I am inclined to regard the underlying cause as a germinal variation or hereditary predisposition. In many cases the occurrence of hernias in other parts of the body is due to a constitutional predisposition, and that this is often hereditary has been shown convincingly by genealogical statistics. In the case of a lesion so little observed as diverticula formation in the intestine, there is, of course, no statistical evidence that the element of heredity plays any part, nevertheless it is perfectly reasonable to suppose by analogy that the predisposition is germinal in nature. It has been shown that the more recently acquired organs are correspondingly more susceptible to germinal variations. One would, therefore, on the hypothesis that the predisposition to diverticula is a germinal variation, expect to find its occurrence commonest in the sigmoid, which, being derived embryologically from the hindgut, is the most recently inherited portion of the intestinal tract.

The early investigators differed as to whether diverticula were formed by traction from without or by pulsion from within. Certain forms of diverticula are caused obviously by the traction of tumors or adhesions, but these do not come within the scope of this paper. It is conceivable that the diverticula of the small intestine may be caused by traction. The tremendous tractile force which the mesentery of the small intestine exerts on the gut during great distention is suffi-

ciently familiar to surgeons. The diverticula in the free border in the large gut, on the other hand, can be formed in no other way than by pulsion. Apparently the amount of pulsion necessary to produce diverticula does not need to be extraordinary. Given the predisposing factor of innate local muscular deficiency, the ordinary pulsion that normally exists in the bowel is sufficient to bring about the result. This is illustrated by Case 1 reported in this article, where the patient had always enjoyed excellent digestion and had all her life been unusally free from constipation or abnormal gas formation. An analogous instance is the gradual development of femoral or inguinal hernias in individuals who have never been subjected to strains, and who on account of an inborn local tissue deficiency are subject to the formation of hernias from ordinary intra-abdominal pressure.

A sufficient number of cases has been now collected from the operating room and from the pathological laboratory to show evidence that probably most people having diverticula suffer no harm from them. Diverticula of the small intestine appear to be almost without danger. Sampson's case where a thickening and kinking of the mesentery beneath the diverticula caused an obstruction of the bowel is the only recorded instance where this lesion occurring in the small intestine has given rise to symptoms. In all other cases where symptoms have arisen, the diverticula have been situated in the large intestine and usually in the region of the sigmoid. The reason for this is that the diverticula of the small intestine, unlike those of the large intestine, do not harbor feces, partly because of the more fluid nature of the fecal contents, and partly because the openings are less likely to be constricted, as has already been noted. In addition to this, Sampson points out that a diverticulum lying protected by the side of or between the leaves of the mesentery is less likely to become inflamed than one lying loose upon the free border of the intestine.

The mode of infection of diverticula is obvious, being similar to that of appendicitis. The diverticulum, at first microscopic, becomes gradually pushed out into a pouch with a constricted opening. This pouch becomes a receptacle for feces which are not evacuated on account of the constriction. The fecal contents, decomposing and hardened, become a nidus for various bacterial flora, and the concretion thus formed, irritating and ulcerating the mucous lining of the diverticulum, spreads infection by the lymphatics to the neighboring wall of the gut and to the peritoneum, or else actually perforates the wall of the diverticulum and causes a local abscess. Such an abscess may develop into a general peritonitis, or it may adhere to some hollow organ, more often the bladder, and discharge into it, and cause a fistula; or the abscess mass may absorb spontaneously. Heine has collected eight cases of enterovesical fistulæ which were proved to result from the adhesion of a suppurating diverticulitis to the bladder. Undoubtedly many of the cases of gas and feces in the bladder have a similar origin. Hochenegge and Griffin have described cases where carcinomata have developed from diverticula.

The symptoms of acute diverticulitis are pain in the left side, with the formation of an inflammatory mass which can sometimes be felt through the left flank. In my case it was felt in the posterior cul-de-sac slightly to the left. Comparing this case with others, it seems to be fairly common to find the mass situated there in women. In my case the sigmoid was abnormally long. Whether this is a frequent occurrence does not appear in the literature, no note having been made of it, but it would be interesting to know if this anatomical feature has any pathological significance. One would expect with such a long freely movable sigmoid a greater tendency to mechanical impairment of the circulation and a greater consequent danger of an inflammatory process if diverticula be present.

In making the diagnosis of diverticulitis, it should be remembered that although the disease is more common than has been supposed, it is nevertheless comparatively rare, and every left-sided pain is not to be regarded as diverticulitis. As a matter of fact, the inflammations of the sigmoid are not yet thoroughly understood. The inflammatory tumors described by Braun and more recently by Myer which exhibit a general fusiform and local swelling about the gut somewhat resembling diverticulitis appear to have a mysterious origin and one is at a loss to account for the chronic adhesions about the sigmoid occasionally seen during pelvic operations where origin from a salpingitis may be ruled out.

Although the symptoms of diverticulitis resemble left-sided appendicitis, the treatment is considerably more complicated. If an abscess is present, it must be drained through the abdominal wall, in which case a fecal fistula usually ensues, which has much less tendency to heal spontaneously than corresponding fistulas that may follow acute appendicitis. It then becomes necessary later to resect the bowel in order to close the fistula. In case the inflammatory process has not gone too far, Dr. W. J. Mayo recommends resection of the bowel at the first operation, which may result in primary union and a rapid convalesdence. Dr. Mayo describes several cases which presented the symptoms of left-sided pain and an inflammatory mass which subsided without operation and without recurrence. These cases he regarded as probable instances of acute diverticulitis with spontaneous cure. The possibility of a spontaneous cure should, therefore, always be born in mind.

The following cases are presented as a contribution to the rapidly increasing number of reports that are being made of the condition of diverticulitis. Case 1 occurred in my own practice. The other cases with the exception of Case 12 were furnished by the courtesy of Dr. D. F. Jones, Dr. J. T. Bottomley, Dr. Maurice H. Richardson, Dr. C. A. Porter and Dr. F. B. Lund. I am especially indebted to Dr. C. A. Porter for the rare

case of carcinoma associated with diverticulitis. This case, so far as I can learn, is only the fourth of its kind that has been reported, and will later be described in fuller detail by Dr. Porter with a discussion of the relationship of carcinoma to diverticulitis.

CASE 1. Mrs. F., seen in consultation with Dr. W. L. Richardson and Dr. H. T. Swain. Patient had suffered from deep left-sided pain for about a week; pain was increasing in severity, temperature 100°. Abdominal examination showed some tenderness on deep pressure in the left pelvic region. Vaginal examination disclosed tender mass behind the uterus and extending to the left.

*Diagnosis.* — Probable pelvic abscess. Patient, a large, well-nourished woman with considerable but not excessive fat, had had pneumonia one and one-half years previous to examination, and since then had dieted for diabetes. At the time of the operation patient's urine contained 4% of sugar.

Operation, April, 1909, Trendelenburg position, median incision. Intra-abdominal fat found to be excessive, and the large intestine completely incased in fat. A rounded mass felt in the posterior cul-de-sac adherent to the posterior wall of the uterus. On freeing the adhesions this mass was found to involve a much elongated loop of the sigmoid which was completely free and the mass brought through the wound for inspection. On freeing away the fat which surrounded the mass, it was found to consist of a necrotic, purulent, granulating tissue at the base of which was a circular opening into the intestine. The opening was on the free border. In the neighborhood of the necrotic area were two small diverticula which, though involved in the adhesions, were not themselves actively inflamed. No other diverticula could be detected in the length of the sigmoid, although the thick investment of fat might easily have concealed them if small and not inflamed. The two small diverticula were tied off and as much of the necrotic granulating tissue cleaned away as possible. A loop of intestine was attached near the edge of the abdominal wound by a catgut stitch and a Penrose drain left in. Patient did well for four days, when a fecal fistula became established and at the same time a deep infection in the abdominal wall to the left of the fistula. The fistula became a large one, and for a time discharged all the contents of the bowels. Later this fistula partially closed, but not completely. Sugar disappeared from the urine three days after the operation and did not appear again until nine months after, when it again made itself evident, and at the same time the fistula, which had never completely closed, became more patent and the patient's general condition began to depreciate. The second operation was performed by Dr. Charles H. Mayo in March, 1910. The old incision was reopened and the numerous adhesions about the intestine freed. Two small diverticula were found in the same location as at the first operation. A second diverticulum about two inches long, which had not been palpable at the first operation, was found at a point near the rectum in a process of active inflammation. This diverticulum was removed. The portion of the bowel which contained the fistula and the two small diverticula was then resected and an end-to-end anastomosis performed, a large rubber tube being left in the intestinal canal. The upper end of this tube was sewed to the proximal segment of the bowel and the tube then drawn down so as to invaginate the bowel in the manner of an intussusception at the level of the anastomosis, according to the method devised by Dr. W. J. Mayo and described in the *Annals of Surgery*, February, 1910. The patient recovered well from this difficult operation, but the fistula became again re-established and has not to the present date completely healed. In October, 1910, the patient developed a cystitis and was conscious of passing gas through the urethra. The cystitis has yielded to treatment and no fecal material has ever been discovered in the contents of the bladder. Sugar disappeared from the urine for several months after the second operation. The presence of sugar in this case has been a serious handicap to the patient, and its disappearance for several months after each operation is a matter of speculation.

CASE 2. Contributed by Dr. J. T. Bottomley. Transcribed from the records of the Carney Hospital.

C., age forty-five. Diagnosis: Sigmoiditis, diverticulitis. Operation: Resection of sigmoid; end-to-end anastomosis, June 20, 1909. Incision slightly to right of median line below umbilicus. Abdomen very fat. About middle of pelvis was a hard, smooth mass size of a tennis ball. Mass was adherent to the sigmoid and to the bladder by rather free adhesions. These were broken. About four inches of the sigmoid with the mesentery (including the mass) resected with the end of the arm and sutured into side of lower arm (the end of which was crushed and turned in a clamp which was on upper arm). One could not be used on lower arm. The mass was about fifteen inches from anus. The tabs on the sigmoid were very numerous and very large and were freely removed before the anastomosis was attempted. Layer suture of abdominal wall. Rubber tube with gauze brought out the lower end of incision. The lumen of the intestines were absolutely unobstructed. A small opening slightly larger than a probe led into mass. Mass not opened. Specimen sent to Harvard Medical School.

June 27. Patient suffers from gas pains. Abdomen considerably distended. Wound discharging a small amount of fecal material.

June 30. Wound discharging fecal material freely. Incision clean.

July 2. Temperature 100°. Wound discharging fecal material freely.

July 7. Complains of tenderness on pressure about four inches to left of incision.

July 9. Tenderness present. Fecal fistula discharging freely.

July 12. Under ethyl chloride anesthetic a small incision was made over point of tenderness and about ℥ss of foul discharge evacuated. A small split rubber tube placed.

July 15. Fecal fistula discharging freely. Small amount of discharge from second incision.

July 19. Clean edges drawn together with adhesive strips. Fecal discharge cleaning up.

July 22. Fecal discharge very slight. Wound on left all filled in with healthy granulations.

July 25. No fecal discharge present for forty-eight hours. Small amount of sero-purulent material expressed from fistula.

July 28. Small amount of sero-purulent discharge coming from fistula. No fecal material.

Aug. 1. Small amount sero-purulent discharge from wound.

Aug. 3. Small amount discharge from wound.

Aug. 5. Almost no discharge.

Aug. 8. No discharge.

Aug. 10. Wound apparently solidly healed. Discharged. Relieved.

CASE 3. Contributed by Dr. D. F. Jones.

W. B. H., age sixty-nine, married, seen on Aug. 20, 1910.

*Family history.* — Negative.

*Past history.* — Has had partial prolapse of uterus since birth of last child, thirty-five years ago. For a number of years has had tenderness about the lower abdomen and inability to walk without discomfort. Hypertrophic arthritis.

*Present illness.* — For nearly a year patient has complained of increased tenderness in the lower abdomen, especially on the left side, where it seems to be very sensitive. This pain on the left is markedly increased by walking, but she is able to ride in an automobile without any discomfort. No urinary symptoms. Bowels absolutely regular without medicine. Digestion good. Appetite good. No loss of weight.

*Physical examination.* — Well developed and fat woman with large abdomen. By vagina a mass high up in the left posterior cul-de-sac, which feels hard and lobulated, can be felt. This mass is somewhat tender. Perineum torn. Some bulging of the anterior vaginal wall. Cervix comes down easily into the introitus. Abdomen negative. Heart, soft systolic murmur. Urine, normal. Operation, Aug. 23, 1910. Median incision. The intra-abdominal fat much increased. On the left side of the pelvis a hard mass, firmly adherent to the posterior and left wall of the pelvis, can be felt. This mass proved to be about the lower end of the middle third of the sigmoid. This adherent mass was separated and brought into the wound. Extending along about four inches of the sigmoid on the mesenteric side could be seen numerous small rounded masses. Pressure upon some of these masses showed them to be soft, and one could almost invert them into the bowel. The appendices epiploicæ and the fat of the mesentery were hardened and covered with adhesions in this area. The wall of the bowel seemed a little thickened except for the mesenteric border, and the lumen only slightly narrowed. As none of the diverticula seemed to be perforated or inflamed, it was considered safer for the patient to bring the mass forward to the anterior abdominal wall without doing any more extensive operation. Convalescence was uninterrupted.

Case 4. Contributed by Dr. C. A. Porter. Transcribed from a personal letter.

Charles S. B., formerly a patient of Dr. Henry Jackson.

Patient was a well-nourished and developed man of seventy-two, rather sedentary habits with pretty well-marked arteriosclerosis for several years.

Operation, July 28, 1909. For the past three years patient has had increasing constipation, for which he had to take Kutnow's powder every morning. He would have three or four loose movements, and from time to time, when questioned after the operation, recalled having passed small fecal nubs about the size of sheep's dung. He noticed at times that there was rather a bad odor to the dejections. He had tried taking injections, but found that the rectum tended at once to expel fluid, if put in at all rapidly in excess of a pint and a half. Dr. Jackson told me that, during the winter of 1909, he had felt a mass in the left lower quadrant, which he thought was in or adherent to the abdominal wall. In view of the patient's age, and the probability that it was malignant, he did not believe in any operation so long as the bowels acted sufficiently well.

I saw the case in consultation with Dr. Percy Musgrave at Bass Rocks on July 27. At this time patient was slightly nauseated; had had no movement of the bowel for two days; was obviously obstructed by a growth which seemed to me situated in the sigmoid flexure, and was probably carcinoma. I operated through the left rectus. On opening the abdomen, I found a very large indurated mass with extraordinarily big appendices epiploices. This mass was adherent to the anterior abdominal wall, just to the inner side of the left anterior spine, where infection had occurred and yellowish fibrin with a small amount of pus lay between the gut and what had been the peritoneum. Over this point there was distinct tenderness at the time of operation, but, if I recall correctly, the patient had no fever. Near the pelvic brim there was a constricted area which felt like carcinoma, and above this for a distance of six or eight inches there was well-marked diverticulitis. In some of the cavities, hardened fecal masses could be felt. I resected about ten inches of the intestine, bringing up the distal end of the bowel to the lower end of the wound, and the lower part of the proximal bowel to the upper part. I was unable to remove all of the diverticuli, which extended up almost to the splenic flexure. The artificial anus worked very well, and the patient in spite of age made an uninterrupted convalescence. From time to time he has had slight discharges of pus from anus, as if the diverticula remaining in the lower portion of the bowel became occasionally infected. An end-to-end suture was considered, but, owing to the conditions present, was advised against.

CARCINOMA ASSOCIATED WITH DIVERTICULITIS.

Case 5. Contributed by Dr. C. A. Porter.

A. A., aged fifty-six years, patient of Dr. Maxwell, of Grafton, Mass.

*Present illness.* — For years has suffered from indigestion, constipation and for the last two or three years, a great deal of depression with suicidal tendency. As he looks back at it, he first noticed symptoms of increasing obstruction about a year ago, with small, tape-like stools and excess of mucus. In the past four months, there have been two attacks accompanied by distention, peristaltic pain, nausea and vomiting, which passed off with loose dejections. For two months there has been some blood and mucus in the stools. The pain has been across lower abdomen, and also low down in the sacral region behind; the latter pain was more or less steady and the former colicky, and, with any tendency to obstruction, very severe. He had been examined a few weeks ago by a doctor, who said there was a growth in the rectum. He has lost about ten pounds in weight during the last year, due, he thinks, to the fact that he has regulated his diet in order to avoid attacks.

*Physical examination.* — Mild mannered, depressed man; logy, fat and flabby. Heart and lungs negative. Urine negative. Abdominal examination shows nothing abnormal; no peristalsis can be made out; slight tenderness in the right iliac fossa, low down. By rectum, there is a distinct, indurated mass which will not admit finger tip; it is felt from three and a half to four inches from the anus. This seems to be slightly mobile from side to side; blood follows examination. Examination of stools shows large amount of mucus and blood. No hemorrhoids present.

After long discussion, patient consented to an operation, and to leave to my judgment what should be done.

Operation at 38 Newbury Street, Sept. 17, 1908. Drs. Whitney, Maxwell and Clapp present, the last two of Grafton, Mass.

Under ether, the mass is felt as before described with greater distinctness. Bimanual examination, pressing down from above, shows mass to be slightly mobile from above downwards and from side to side. A few glands can be felt on the side of pelvis. Considerable

bleeding was a result of examination and following curetting of a portion, which Dr. Whitney examined at once and reported to be adenocarcinoma. For some reason, patient collapsed, and it seemed for a few moments as if no further operation could be done. Under strychnia he improved slightly, and I decided to do a rapid colostomy. Incision made along inner border of left rectus, five inches long. On examination, the appendices epiploices were very large and fat; sigmoid elongated and filled everywhere with various sized diverticula, many of them projecting under mesenteric attachment, some into base of appendices and others free on the surface of the bowel. Some of them contained hard enteroliths. There were evidences of past infection, shown by adhesions about the rectum in the pelvis. The subperitoneal fat was unusually developed everywhere. Just above the pelvic part of the rectum, in the peritoneal cavity, could be felt a mass about the size of a small lemon, which was movable with one or two glands on either side. It seemed unwise to perform a colostomy in the midst of diverticulitis, so sigmoid and lower part of descending colon were freed, above which point the diverticula were very infrequent. A suture was placed about bowel, which was then cut and disinfected with carbolic acid. The proximal end was carefully sutured to the peritoneum, and, owing to patient's condition, it seemed at first unwise to do anything more, but he gradually improved and I decided to complete operation at this sitting. The vessels going to the sigmoid were, therefore, tied to abdominal incision, and the sigmoid and rectum cut loose from the peritoneum and the glands and mesorectum were scooped out from the pelvis. The abdominal wound was then carefully sutured above emerging bowel, and distal end dropped into pelvis. Patient was then placed in lithotomy position, and incision made above anus, removing the sphincter muscles. There was considerable bleeding, which was tied with catgut, then the whole rectum was removed by blunt dissection, scooping it out from the pelvis, and after this maneuver, bleeding was surprisingly slight. Cavity left was packed with two large handkerchiefs of gauze.

*Convalescence.* — Patient went to bed in good condition; pulse 120. No explanation made of peculiar failure in the beginning of etherization. In afternoon, patient began to recover from the ether, and vomited tarry blood. This weakened him very much and lasted for about fourteen hours; no diagnosis as to the cause could be made. It would seem possible that a hemorrhage into the stomach had taken place and caused collapse before mentioned. On the following day, vomiting had ceased, since which time patient has made a normal convalescence. Frequent movements of bowels show some tarry material. Dressing has not been changed, but, on Sept. 22, is beginning to show some signs of decomposition. Temperature at no time was over 100, and has gradually dropped to an average of 95.

Examination of tissue by Dr. W. F. Whitney: Specimen consists of about 25 cm. of the lower end of the rectum with the anus. About 19 cm. above the anus was a circular infiltrating and ulcerated new growth about 3 cm. in greatest diameter, with slightly raised and thickened edges.

Microscopic examination of a portion of the base showed an irregular growth of tubular gland tissue infiltrating in the submucous tissue. Diagnosis: Adenocarcinoma.

Above this there were numerous small tube-like diverticula from the wall of the gut into the fat tissue. Diagnosis: Chronic diverticulitis.

CASE 6. Contributed by Dr. F. B. Lund.

J. H. G., physician, age fifty-two years. Had suffered for about two weeks from abdominal pain, especially on movement of the bowels. His temperature was about 100° in the evenings, normal in the mornings. The urine was normal, stools did not contain blood. Extensive hemorrhoids were present. He had been constipated for a long time, but had never had diarrhea. No loss of weight. Tender sausage-shaped mass could be felt in the left iliac region. Diagnosis lay between an inflamed malignant growth and diverticulitis. Operation, April 13, 1908. An indurated malignant-looking mass occupied about three inches of the sigmoid. The induration extended into the mesosigmoid. About four inches of the sigmoid with the mesosigmoid were resected and an end-to-end suture done with one layer of Connell sutures of catgut surrounded by a Cushing suture of linen thread. Abdomen closed without drainage. The specimen removed was very much indurated and thickened and greatly resembled malignant disease. It was carefully examined and sectioned by Dr. Mallory, and drawings made of the diverticulum extending down through the walls of the bowel into the mesentery. Microscopical examination showed no evidence of malignant disease. The patient made an uneventful recovery and has since been well and actively engaged in the practice of his profession.

CASE 7. Contributed by Dr. F. B. Lund.

Mrs. M., age sixty-two years. Seen in consultation with Drs. J. F. Welch, of Quincy, and F. W. White, of Boston, in 1907. Had suffered for five years with attacks of abdominal pain said to have been inflammation of the appendix. A year and a half ago began to pass bloody mucus in the stools intermittently. One year ago passed a great deal of mucus for a few days. Her attacks of pain were attended by a desire to have a stool. For the last few months she had noticed that her stools were bloody and ribbon-like. She had to take cathartics constantly. After a thorough clearing out she would pass dark clots and bloody mucus. Examination showed that she was large and stout, weighed 199 lb. The prominent abdomen was slightly tender over the pelvis. No definite mass could be felt. Rectal examination was negative except for old internal piles. Examination with proctoscope showed nothing for a distance of two inches. Stools were of normal color and consistency, but of small caliber and contained mucus, blood and pus. The blood was found on a meat-free diet. Careful regulation of the bowels and careful diet failed to relieve her symptoms, and after about three months of medical treatment she still suffered from attacks of severe colic and passed mucus and bloody stools. In one of the attacks she had a slight temperature. Vaginal examination showed nothing abnormal to be felt by rectum. Diagnosis lay between colitis, diverticulitis and carcinoma. Operated on Nov. 11, 1907. Median exploratory incision showed a mass in Douglas's cul-de-sac covered with tags of fat which were indurated at the adhesions, which indicated old peritonitis. The uterus was atrophied and had a small fibroid in the fundus. There were no adhesions to the uterus or the ovaries. All the adhesions were between the lower part of the sigmoid and the posterior pelvic wall. In the middle of the fatty mass was a small indurated area which was incised, feces escaping. A probe entering the opening ran downward into the bowel. The diverticulum, for such it was, was wiped out, and inasmuch as the opening in it was too friable to hold sutures, it was closed over by sewing the tags of fat which covered it across the opening. The operation was difficult on account of the obesity of the patient, the amount of fat in the mesentery and the depth of

the pelvis. The pelvis was thoroughly washed out and three iodoform gauze strips were carried down to and around the opening. She recovered from the operation about as was expected and has since continued to suffer from attacks of pain and partial obstruction. It seems to me that the only way to relieve her safely would be to make an artificial anus, but this she does not desire to have done. She sometimes requires morphia for the pain and has constantly to depend on cathartics for any degree of comfort.

Case 8. Contributed by Dr. Maurice H. Richardson.

Mr. H., fifty-two years. Patient of Dr. Holmes, Minneapolis. History taken March 14, 1910. No serious illness or injury except a broken ankle. Travels all the time. Five or six years ago began to have attacks of fever, sudden. Temperature, 104°–105°. Different treatments. One year and a half ago began to have very severe pain in bladder. Sat up all night to strain a drop of urine. The urine was dark colored, with a deposit of white pus. Treatment by Dr. B., of Chicago, for two months, washouts and uroseptin. Said in four weeks he would be well, but was worse. Question of stone in kidney arose. With uroseptin, no fever. Stopped traveling on that account. Went to Dr. Cabot. He was away and he went to Dr. Binney. Same treatment as in Chicago. X-ray by Dr. Dodd showed no stone. Has had cystoscopy. Guinea-pig test showed no tuberculosis. In addition to pus, black specks and chunks of feces. By cystoscope Dr. Binney found an opening in bladder. Dr. Binney said, no use in treatment — operate. No history of appendicitis. During these last two years testicle has swelled up a half dozen times. Gets up at night four times.

Examination of urine, March, 1910: Normal, cloudy, acid, 1015, slight trace of albumen, no sugar, many pus and blood cells, occasional small round cell, rare hyaline cast.

Cystoscopic examination by Dr. Chute showed a puckered scar in upper part of bladder with a drop of pus exuding from it.

*Operation.* — Median incision above symphysis five inches long. Rectum at its upper part found adherent to bladder. At this point there was an inflammatory mass thickening the whole rectal wall. This mass was firmly adherent to the bladder by old adhesions. The adhesions were separated and the rectum was slowly dissected away from the bladder. A small abscess cavity was found in the center of the mass which contained about two drams of pus. Leading into this cavity were two perforations of rectum about one-fourth inch in diameter, and one small perforation into bladder. The rectal wall throughout its circumference was thickened, hard and infiltrated. The perforations into the rectum were lined with mucous membrane and resembled diverticula. The case seemed probably an abscess from infection of diverticulum with rupture into the bladder. The appendix was negative. The perforations in the rectum were closed with chromicized catgut with some difficulty, owing to the hard rectal wall, which could not be folded. The fat of the epiploic appendages was sutured over them. The perforation into the bladder was closed with chromicized catgut and the peritoneum as far as possible sutured over it. Cigarette wicks were placed to the rectal perforations. Wound partly closed with chromicized catgut and through-and-through of silkworm gut. Patient put on constant drainage through urethra.

After operation the patient did well. There was a small amount of fecal discharge through abdominal wound after removal of wicks about the eighth day. Patient discharged on thirty-first day, with clear urine and a small abdominal sinus which discharged occasionally a small amount of fecal matter. This sinus persisted about the same through May and June. During July there began to be evidence of escape of fecal matter into the bladder. There was the occasional passage of gas by the urethra, with attacks of cloudy urine, and fever. Particles of fecal matter were found in the urinary sediment. The abdominal sinus persisted with a daily small amount of fecal discharge, just enough to stain the gauze slightly.

Second operation, Aug. 19, 1910, Corey Hill Hospital. Median incision through the old scar. Sinus followed down by dissection. Bladder adherent to rectum. Old adhesions of intestines in pelvis. Adhesions separated. Probe passed readily through small sinus into bladder, indurated bladder wall resected, leaving one-inch opening. This was closed with continuous chromicized catgut to mucous membrane, and interrupted chromicized catgut to bladder wall. A sinus was found extending into rectum. Below this point the rectum was surrounded by considerable indurated tissue, forming a moderate stricture. This inflammatory tissue was dissected away from the rectal wall, and all the indurated tissue around the sinus was resected. In doing this a non-inflamed diverticulum about one-eighth inch in diameter and one-half inch long was cut across. An opening about one and one-half inch in diameter was thus made in the rectum. This was closed by continuous chromicized, covered with chromicized catgut Lembert sutures. Two cigarette wicks. Wound closed with silkworm gut through and through. Chromicized catgut to fascia.

Suprapubic cystotomy wound made, and rubber tube stitched in bladder.

The patient's general condition was good after the operation. There was some temperature. The wicks were removed on the sixth day and rubber dam replaced. On the twelfth day there was fecal discharge through the wound.

On the fourteenth day in the evening there was sudden severe pain in the left side of abdomen, with persistent vomiting. The patient's condition became bad. There was evidently a peritonitis. On the morning of the fifteenth day the abdomen was rapidly opened again for drainage.

Microscopical report: Chronic inflammation. (Dr. W. F. Whitney.)

Third operation, Sept. 3, 1910. Incision along outer border of left rectus muscle. Much pus found. Source not made out. Two large gauze wicks. Similar incision on right side. Thinner pus found. Wicks placed toward pelvis. Wound not sutured.

The source of the peritonitis was not made out at operation. It obviously arose from the pelvis. No search was made for the cause. The abdominal cavity was drained as rapidly as possible. The patient failed steadily and died thirty hours later.

Case 9. Contributed by Dr. Maurice H. Richardson.

Mr. W., seventy years, patient of Dr. N. J. Davis, Somerville. Oct. 6, 1908. Taken day before yesterday with pain in epigastrium shifting to right iliac fossa, with right-sided tenderness, rigidity without distention. Diagnosis by attending physician, "acute gangrenous appendicitis." Confirmed by Drs. M. H. and E. P. Richardson, and two other doctors present. White count, 17,000. Temperature, 100.8. Pulse, 80.

Rectal examination showed a resistant tender tumor at right pelvic brim.

Operation at Corey Hill Hospital, October, 1908. Ether by Dr. Garland.

Examination showed moderate distention, marked tenderness, with little spasm over abdomen, some on right. Marked tenderness by rectum, which was ballooned. A mass like appendix felt by rectum.

*Operation.* — Right rectus incision five inches long. Free pus in peritoneal cavity. Intestines reddened. Appendix retrocecal, running upward along outer side of cecum, thin and pale. Much pus with fecal odor in pelvis. Adherent to rectum, two inches peritoneal reflection on pelvis floor, was a reddened, indurated mass, partly gangrenous, about the size of a plum, an enlarged and inflamed epiploic appendage. Some coils of intestine were adherent to it by recent adhesions. On separating the appendage from rectum a small cavity the size of a cherry was opened. This apparently communicated with the bowel, although it was not proved to do so and was thought to be a diverticulum. The peritonitis was due to bacterial leakage through an area of gangrene. A rubber tube was inserted into the small cavity and walled around with four gauze wicks. Sutures through and through of silkworm gut and chromicised catgut.

A fecal fistula developed at about the fourth or fifth day. The patient apparently did well in spite of this for a time, but then gradually became weak and drowsy, and died on the twenty-second day after operation.

CASES PROBABLY DIVERTICULITIS BUT WITHOUT DEFINITE DIAGNOSIS.

CASE 10. Contributed by Dr. D. F. Jones.

J. I. R., teacher, forty-five years, married. Seen on June 26, 1905.

*Family history.* — Negative.

*Past history.* — An attack nine months ago, similar to the present. Relieved by dose of castor oil. Has always been constipated. About four weeks ago patient fell in a boat, coming down on the edge of the seat. Has been somewhat sore over the coccyx ever since. Has not been feeling well for some months because of indigestion and palpitation. This, however, is the usual condition at the end of the school year. Eight days ago awoke in the morning with a feeling of pressure in the region of the bladder. Since then has felt like walking in a stooping position, and has had to be careful of walking because of the jar. The night following the first symptoms he had some pain in the lower abdomen which seemed like gas pain. When the gas reached a certain point the pain would be quite severe. The pain in the bladder has diminished somewhat, but the pain above the bladder has been worse for the last two days. Yesterday took castor oil, ounce one, which caused great pain. Patient has been up and down, occasionally going to his office since this first attack of pain. Two days ago saw the doctor because of increased pain, and went to bed that night. Next day temperature was up to 100° in the morning, and gradually rose all day to 102. This morning temperature was 100.6°; to-night, 103°.

Abdomen distended and tender with some rigidity extending across the lower abdomen, perhaps slightly more low on the right just above the pubes. By rectum, ballooning was marked, with floor of pelvis tender and firm.

*Operation.* — Right rectus incision. The whole lower abdomen from umbilicus to the pubes, one mass of adhesions. On the right, close to the bladder, was a large abscess filled with foul pus. On the left was a large hard mass extending from the base of the bladder to the left iliac fossa. This mass was at least three inches in diameter, fusiform in shape, and proved to be the upper portion of the rectum. It was felt at the time that this mass must be malignant disease which had broken through into the pelvis. The pelvis was drained by two large gauze wicks.

Patient picked up slowly in general condition, and at the end of five weeks the abdominal wound had entirely closed. Since that time the patient has been in excellent condition, with the exception of two attacks of marked constipation and discomfort in the pelvis. The last examination was in May, 1910. No masses could be made out anywhere in the pelvis. His condition was excellent except for rather marked constipation.

CASE 11. Contributed by Dr. D. F. Jones.

Mr. F., fifty-three years, conductor. July 30, 1904.

For several years has had indigestion. Never had any attacks similar to the present. Bowels always slightly constipated. No diarrhea until three weeks ago, when he had an attack lasting about one day. Stools were watery and bloody. Thinks he has lost some weight, though he has not been weighed. Six days ago began to have some pain just above pubes. Went to work next day, but had to quit on account of pain. Consulted a doctor the next day, but was not relieved. Four days ago, in addition to pain, which was continuous, began to have considerable pain on defecation and micturition, and this has continued since. Bowels have moved daily with cathartics. Temperature yesterday, 100. This morning, 101. Whites, 19,000. About noon to-day, pain ceased.

July 31. Slightly obese man, nothing abnormal found in chest. Seems rather bright and restless, not apparently in pain. Abdomen not distended. Moderate tenderness over whole pelvis, no rigidity, no mass felt.

Rectal examination shows marked tenderness in both sides, no mass felt. Passed normal urine without difficulty. Temperature, 103°. Pulse, 100. Whites, 16,000.

*Operation.* — Median incision four inches long below umbilicus. On opening peritoneum intestines appeared collapsed and normal. General peritoneal cavity walled off with mass about size of hen's egg felt deep in pelvis adherent to rectum. This was brought up with some difficulty and found to be attached to sigmoid about its middle. The mass apparently consisted of appendices epiploicæ matted together about the base. This was opened and about ʒii foul fecal pus containing a small fecal concretion evacuated. Some of the tissue cut away for examination. No opening found into bowel. Wick placed to pelvis bottom. Second wick to mesentery on sigmoid, which was somewhat torn below base. Third wick to pus cavity. Wound closed about wicks with through-and-through silkworm gut. Smears made from pus showed many micrococci and colon-like bacilli.

Aug. 1. Considerable discharge.

Aug. 3. Ends of wicks cut off and picked loose. Still considerable discharge. Wicks out. Thick pus discharge.

Aug. 15. Wound granulating well. Free discharge for past week.

Aug. 22. Wound again wicked for several days.

Aug. 26. Wick gradually shortened. Less discharge.

Aug. 29. Small sinus remains.

Aug. 30. Granulating wound with small sinus from which patient feels gas escape when bowels move.

Dr. Jones has opened the scar once or twice in outpatient department. Since leaving hospital wound has opened and closed with discharge of varying amount of pus. No fecal matter observed.

From pelvis: An irregular mass 2 cm. in diameter of acutely inflamed fat in which were small hemorrhages, the outer surface of which was covered with an acute fibrinous exudate.

### DIVERTICULA OF THE APPENDIX.

Case 12. The following case does not come strictly under the subject of the paper, but is added to illustrate the occurrence of diverticula. The appendix here described was removed by me during an hysterectomy for fibroids of the uterus on Nov. 10, 1908, and is transcribed from the pathological report by Dr. H. T. Hutchins.

Vermiform appendix measures 5 cm. in length and there is a small bit of fatty mesentery attached. The proximal two thirds of the appendix is swollen. At the junction of the middle and outer one half of the appendix there spring from the wall of the appendix two nodules, one about 5 mm. in diameter. These nodules are rather dark in color, veins show prominently through the surface, are covered by a smooth and very thin peritoneum, and resemble a rupture from the vermiform appendix itself, the rupture not going through the peritoneum but having pierced the muscle and subperitoneal tissues. Distal to these nodules the vermiform appendix is very small and atrophied. On longitudinal section of the appendix the lumen of the proximal two thirds is found to be patent and contains fecal material. In the tip the lumen is closed. The two projections noted above are found to be connected with the appendix and are apparently herniæ of the appendix and are lined by a mucous membrane. Section taken of uterine wall including endometrium, myoma, cystic right ovary, left tube, cervical polyp, cross section of hernia of appendix wall, also appendix wall itself.

*Microscopical examination.*—Section near the base shows a normal appendix, normal mucous membrane thrown into folds. Section of the appendix through the herniæ shows a true hernia of the mucous membrane through the walls under the peritoneum. The muscle of the wall of the appendix grows gradually thinner and thinner until it vanishes, and over the top of the hernial body there is nothing but peritoneum and loose subperitoneal tissue covering the mucosa. There is no evidence of scar tissue in the wall of the appendix, and the appendix is otherwise normal.

### SUMMARY.

*First.* The clinical significance of the acquired diverticula of the intestine has only recently been recognized.

*Second.* The acquired diverticula of the intestine are nearly always multiple and may occur throughout the length of the intestine, though most commonly in the sigmoid flexure. The diverticula of the large intestine are of more important clinical significance than those of the small intestine.

*Third.* The etiology of the formation of diverticula in the intestine is referable probably to an inherent local muscular deficiency. The most common predisposing factor in causation is the accumulation of fat on the intestine, as is shown by the fact that the majority of diverticula of the large intestine occur at the attachment of the appendices epiploicæ.

*Fourth.* The pathology and symptomatology of diverticulitis simulate left-sided appendicitis. Some cases are cured spontaneously without operation.

*Fifth.* The operative treatment of diverticulitis consists in general of drainage in the presence of abscess or gangrene formation. In favorable cases, resection of the bowel and anastomosis is indicated.

## REPORT OF A SERIES OF CASES OF SYPHILIS TREATED BY EHRLICH'S ARSENOBENZOL AT THE WALTER REED GENERAL HOSPITAL, DISTRICT OF COLUMBIA.

BY CAPT. HAROLD W. JONES, MEDICAL CORPS, U.S.A.

(Published by permission of the Surgeon-General, U. S. A.)

The following paper is, needless to say, a preliminary report only, and any conclusions drawn must necessarily be subject to revision as time goes on. Twenty cases only are reported, but all of these have been carefully observed and numerous Wassermann reactions have been made in each case. The writer feels that the time which has elapsed since treatment was begun in the earlier cases (three and one-half months) is all too short for many definite conclusions in the series of cases. At the outset it may be stated that the purpose of this report is not to show what arsenobenzol will accomplish in suppressing the manifestations of syphilis; this has already been shown so conclusively in so many hundreds of cases as to be mere repetition. The main purpose of the paper is to set forth what seems to me the best method of administering the drug, and to draw attention to the subject of relapses and incomplete cures. The data in regard to the cases is presented in tabular form, and for the sake of brevity the most important facts only are included, in order that the table may be readily comprehended.

### METHOD OF PREPARATION OF THE DRUG.

At first the arsenobenzol was prepared in neutral suspension after the method of Wechselmann, but this method was soon abandoned as it was found that it was not readily absorbed, remaining in the tissues for weeks and causing long-continued irritation. For injection into the tissues the capsule containing the drug was immersed in alcohol and wiped with sterile gauze, after which the neck was marked with a file and the top removed. The contents of the capsule was then emptied into a bottle of 50 ccm. capacity, sterilized, and containing a few glass beads at the bottom to assist in the solution of the drug. The bottle used was marked to show the proper level for 10 and 20 ccm. Certain varieties of arsenobenzol required to be first wet with from ½ to 1 ccm. of c.p. methyl alcohol in order to effect solution in hot water, but all that has been used of late has gone into solution quite readily by the addition of 10 to 12 ccm. of hot sterile water. Following this, for each .1 gm. of the drug, there was added about .75 ccm. of a normal (sterile) NaOH solution. This produced a flocculent precipitate which redissolved on the addition of a few more drops of the NaOH. As a rule it was found that the temptation was to add too much NaOH as almost always, if a slight precipitate remained, it would be found that this would be dissolved in five or ten minutes more, thus rendering the addition of more NaOH unnecessary. When the alkaline solution became clear it was brought up to a total bulk of 20 ccm. by the addition of sterile water, and was then

ready for injection into the muscles. Where an intravenous injection was desired, about 350 ccm. of sterile salt solution was added and the whole kept at blood heat.

### METHOD OF ADMINISTRATION.

Leaving out the subcutaneous method with the drug in neutral suspension (Wechselmann's) the arsenobenzol was given in three ways, — intravenously, intramuscularly into the buttock, and intramuscularly into the erector spinæ. The intravenous method was employed seven times in six patients. The fluid was usually about 350 to 400 ccm. in bulk and was at body heat. One of the veins at the bend of the elbow was selected, a rubber tube being wound about the upper arm to cause the vein to show plainly. The accompanying illustration shows the bottle holding the solution. The apparatus figured was devised by Captain Nichols, of the Medical Corps, and has proved very satisfactory. About seven or eight minutes was usually consumed in this method.

The first two or three doses, given by the intramuscular method in the buttock, were given near the ischial tuberosities, but since this forced the patient to use a pillow to sit on for many days, it was abandoned for what has proven a more satisfactory site, namely, a point at the upper portion of the middle third of a line drawn from the anterior superior spine of the ilium and the ischial tuberosity. The injections were always given deep, about 2¾ inches, and the fluid injected very slowly, 10 ccm. in each buttock. Seventeen doses were given, in all, in 16 patients.

Only one dose was given in the erector spinæ muscle. Twenty cubic centimeters were injected deep into the muscle. This resulted in such pain later, and it was so long before the patient could sit up or walk, that the method was at once abandoned, although the initial pain was so slight that the method was at the time regarded with favor.

### RECAPITULATION.

Two patients received one intravenous injection and nothing further; one received two intravenous injections and nothing further; two received one intravenous followed by an intramuscular; one received a subcutaneous injection followed by an intramuscular, and this in turn followed by an intravenous injection; twelve received one intramuscular only; one received two intramuscular injections. This gives a total of twenty patients treated.

### ADVANTAGES AND DISADVANTAGES OF DIFFERENT METHODS.

As has been said, the suspension (subcutaneous) method proved disappointing, practically no favorable results occurring and the hard indurated mass which formed at the site of injection persisted for months in spite of massage. The intravenous method, while accomplishing results very quickly, and having the great advantage of being nearly painless, will, nevertheless, I believe, be restricted to a certain class of cases, namely, those in which cachexia is present and in which a rapid improvement for the time being is desired or in which pain is to be avoided. The intravenous method, while comparatively simple, is at the same time not as well adapted to the needs of the general practitioner. The fact that two frank and unquestionable relapses occurred after this method had been used, in spite of the fact that practically all symptoms had disappeared, makes it appear as if the action of the drug was not long continued enough to cure the patient. At the same time, it has the theoretical advantage of bringing the entire dose of the drug into the blood-stream, which should be ideal for its satisfactory working. Two intravenous injections are probably better than one, and in the one case in which two were given relapse has not occurred as yet.

The intramuscular method causes pain, there can be no denying that; the amount of pain seems surprisingly variable; with some patients the immediate pain is bitterly complained of, with others the pain is worse after an hour or two. A few cases only required an opiate. A rise in temperature was very common, sometimes lasting as long as five days. Swelling of the buttock was usual, but no case of suppuration occurred. Nausea, vomiting and fainting were all observed in the occasional instance in the series, but no really serious or untoward event occurred.

### RESULTS ON THE LESIONS.

These were quite what might be expected, and in all frank cases with visible lesions were uniform. There were but two cases where visible lesions did not disappear, and both of these are at the present time 75% improved, and one has had his second dose so recently that the ultimate result cannot be predicted confidently.

### EFFECT ON THE WASSERMANN REACTION.

In two cases the serum was negative at the time of injection, but in both these it had been positive a short time before and both cases had had specific treatment previously. One of these (911) was interesting in having active throat lesions and a negative serum. All the other cases had positive sera. In eight cases the serum remains positive, one of these cases having had three injections, the first three and one-half months ago; a number of these, however, are now weakly positive and it may be expected that in some the reaction will become negative shortly. Two cases have become negative following an injection, only to become positive later. Nine cases are still negative, one of them having been injected three months ago. In one case only does a definite lesion persist in the presence of a negative serum.

### SHORTENING OF TIME ON SICK REPORT.

A comparison of the length of time on sick report before and after the treatment by arsenobenzol was attempted, but such a comparison is unsatisfactory and hardly necessary since it is

Severe facial neuralgia. Serum + . | Dec. 3, 1910. .5 gm. Intramuscular. Buttock. | Severe pain. Rise in temperature. |

Results in a series of cases of syphilis treated with "606" (Ehrlich-Hata) and the Technique Employed.

obvious that if lesions can be made to disappear more quickly with arsenobenzol than with mercury and iodide of potassium, an individual with syphilis can be returned to duty sooner if the former method is used in his treatment than if the latter method is chosen. Many a mild case of syphilis without lesions hardly needs hospital treatment and hence does not appear on the sick report, while in the series of cases reported were a number of men who if arsenobenzol had not been employed must have been discharged from the service for disability, — at least 20% in this series reported.

APPARENT CURES.

Thirteen patients are regarded as well and have no symptoms at the present time; of these, seven have positive sera and hence cannot be called cured; in addition, in a number of cases insufficient time has elapsed to pronounce judgment. There are two incomplete cures, one of these having a negative serum after one dose with a persistent lesion, while the other had just had a second dose. In two cases the results are not satisfactory on account of the severity and destructiveness of the lesions in one (529) and the presence of chronic cardiac disease in the second (907). In three cases there were frank relapses (881, 870, 732), but in only one case, omitting cases 907 and 529, which are hardly fair to consider, was there an absolute failure, and this was with the subcutaneous method (930).

CONCLUSIONS.

Justifiable conclusions are hard to draw from so short a series of cases, covering a limited period of time, and the reader can perhaps draw his own from the data submitted. It is thought the series of serum reactions given will prove interesting and instructive. The fact that two relapses out of six cases occurred after intravenous injections (33%), while no relapse occurred after an intramuscular injection, is of interest as indicating a choice of methods in favor of the intramuscular. On the whole, from a standpoint of relief from suffering, leaving aside the question of permanent cure, arsenobenzol has been successful, as would be expected from the reports of other observers during the past half year. Finally, the shortening of the time of infectivity of the lesions of syphilis where arsenobenzol is used is of enormous importance in the military service from a sanitary standpoint and would alone, I believe, justify its use, even if a permanent cure were not effected.

ADDITIONAL NOTES.

Since the foregoing paper was written (Feb. 1, 1911) additional data in regard to several of the cases are at hand. Case 930 shortly after Feb. 1 showed a weakly positive serum and was without symptoms of syphilis. At the site of the first injection in the back (Wechselmann's method) there persisted a hard lump, nearly painless. About Feb. 10, he complained of dimness of sight in the right eye. This increased until vision in that eye became almost nil, while the retinoscopic examination showed numerous hemorrhages into the retina. Chronic arsenical poisoning seemed the most probable cause and it was deemed best to at least open the swelling in the back which had persisted for over four months. On cutting into this a mass was revealed which when finally enucleated by blunt dissection showed an encapsulated collection of yellow material representing almost the entire dose of "606" as originally given in suspension. On microscopic examination the yellow granules were plainly visible. It was expected that, this irritant removed, the patient would improve if chronic arsenical poisoning were the cause. This was not, however, the case, for the left eye a few days ago became involved and two or three days before the present writing (March 10) an iritis of the right eye appeared. As the case stands now, it is not clear whether the eye lesions are due to arsenical poisoning from oxidized arsenic remaining in the tissues and being absorbed in small quantities instead of being promptly eliminated or whether they are due to an uncured syphilis. At present the patient is being treated with mercury and iodide, since I have not had the hardihood to give a fourth dose of "606."

Case 732 is absolutely well (March 10), with a negative serum. He also had a persistent lump in the back, and since he had received a suspension of "606" by Wechselmann's method as a precaution, an incision was made into the lump with the expectation of finding unabsorbed arsenic. Nothing was found but a pasty substance which when curetted out did not give the test for arsenic.

Case 860 still has a positive serum but the testicle is normal in size, although a little indurated. This will I believe prove to be a cure.

Case 881 at the time of leaving the hospital had a negative serum and had gained 30 lb.

Case 929 proved deceptive. At the time of leaving the hospital his serum was negative and he presented no symptoms. About Feb. 10, he suffered a complete relapse, but still showed a negative serum. He was readmitted and received an intravenous injection with a prompt disappearance of the headache, and softened areas in the scalp. After two weeks he was thought to be well, but at the present writing he has again suffered a relapse, the serum being still negative. In this case he has not been given a third dose as yet. This is the second case of persisting lesions accompanied by a negative serum.

From the above notes it may be seen that new difficulties are daily arising. With increasing experience my own opinion is that we must withhold judgment upon the merits of "606" for some time to come.

---

THE president of Bowdoin College has issued an appeal to the alumni association for $140,000 for the use of the medical department. The most pressing needs of the institution are new laboratories and improvements and hospital facilities for the establishment of a dispensary in Portland. — *Jour. Am. Med. Asso.*

## LIQUID AIR IN SURGERY.

BY THEODORE CHAPIN BEEBE, M.D.,
*Surgeon to the Boston Dispensary; Instructor in Surgery, Tufts College Medical School.*

THE value of liquid air in various affections of the skin, both congenital and acquired, has been so definitely proved by many observers that it now has a very positive place in the means at our disposal for the treatment of such lesions. The range of usefulness includes the many varieties of naevi, epitheliomata, lupus erythematosus, birthmarks of all varieties, warts, calluses and some forms of chronic inflammation. Of all forms of benign affections, the various birthmarks are the cause of more mental suffering to their unfortunate possessors than almost any other abnormality. By means of liquid air it is possible to remove these blemishes in almost every case in a way which causes practically no pain and which leaves practically no scar. It is of the greatest importance that these lesions be treated early in life while the tissues are soft, in order to obtain the best result. Port-wine marks, in particular, are much harder to eradicate in adults than in young children. Spongy naevi, if not taken early in life, are very prone to enlarge to a point where even excision with a knife is impracticable. Such cases, it is true, leave some scars, but nothing comparable to those following the usual treatment by means of the actual cautery. As for lesions on the face, no treatment yet devised is so satisfactory as liquid air. The use of carbon dioxide snow is attended by great pain, as attested by several of my patients; requires many more applications, and is inferior in all ways to liquid air. X-ray treatment of surface lesions is a long-drawn-out process, with very problematical eventualities. The recurrence of such lesions as epitheliomata and lupus erythematosus among my early cases was due to too short and too light applications of the liquid air. With growing experience and knowledge of the possibilities of liquid air, such recurrences are becoming more rare. It must be distinctly understood, of course, that the writer refers *only* to such cases where there is no metastasis or glandular imvolvement. Applications to the mucous membrane of the mouth can be made easily and safely, and in one case several applications to the sclerotic coat of the eyeball have been made with no harmful results. A short history of several typical cases will be given showing the possibilities of this method of treatment.

### NAEVUS.

CASE 1. M. C., Nov. 19, 1907, one and one-half years old. Naevus approximately 1 inch square on bridge of nose since birth. Extends down to left inner canthus. Greatly dilated, bluish-red superficial vessels. Two applications of liquid air with moderately firm pressure for ten seconds with an interval between of one month were given. When seen six months later there was a thin pinkish-white scar scarcely visible except when the baby cried. At recent accounts the result was perfectly satisfactory.

CASE 2. R. L., March 12, 1908, seven weeks old. Naevus on dorsum of right foot since birth. Area size of twenty-five cent piece, slightly raised above surrounding skin. Lesion entirely removed after one application of liquid air.

CASE 3. P. H., February, 1909, five months. Congenital angioma in center of forehead about size of ten-cent piece. Five applications at intervals of three or four weeks were given. When seen six months ago the slight scar was only noticeable when the child cried.

CASE 4. D. C., March 30, 1910. Age, three and three-fourths years. Angioma on left lower eyelid about $\frac{1}{4}$ in. in diameter. Entirely removed with one application of twenty seconds' duration. No scar visible.

CASE 5. P. B., December, 1907. Age, two and three-fourths years. Naevus on left cheek since birth. At that time size of head of pin. Grew larger and was excised in December, 1908. Recurred and grew rapidly till it was $\frac{1}{2}$ in. long and $\frac{1}{4}$ in. wide. Treated by electric needle with no improvement. After two applications of liquid air the lesion was healed with no subsequent recurrence to date.

CASE 6. F. H., May, 1910. Age, twenty-two years. Student at Radcliffe. Naevus $\frac{1}{4}$ in. diameter on end of nose. One application of ten seconds to naevus, also an application to a brown-pigmented mole on back of left hand. Both healed perfectly. No scars.

### MOLES.

CASE 1. L. D., March, 1909. Age, twenty. Colored. Has a congenital hairy-and-pigmented mole extending from just above hair-line down over right side of forehead and cheek as far as angle of jaw, and backward as far as the ear. Treated year before with $CO_2$ snow for three months. Gave up that treatment because of the pain. Above right eyebrow and below outer canthus are thick papillary areas. Whole area covered with long black hair. Several applications of ten seconds each were made to different areas of the lesion, at intervals of about one month, through the spring of that year, and again the next fall and winter. Many areas of normal skin were produced with very little scarring. During the winter of 1910 was recommended to have x-ray treatment for the removal of the hair over the lesion. Is to report for further treatment. The result so far has been perfectly satisfactory. The liquid air has no effect on the hairs of a hairy mole.

CASE 2. S. H., November, 1909. Age, twenty-eight years. Has two small moles on her nose, and two on the forehead. Completely removed after two applications of fifteen seconds each.

CASE 3. E. H., February, 1909. Age, twenty-five years. Congenital hairy pigmented mole on chin. Five applications over period of two months. Mole disappeared, but hairs remained. Decided to have these removed with the electric needle.

### PORT-WINE MARKS.

CASE 1. J. E., November, 1908. Age, ten years. Since birth has had an irregularly-shaped port-wine mark on right cheek 3 in. long and 2 in. broad at lower end. Had had one liquid air application in New York. Has been given many applications over various portions of the area at intervals since. At present there are many small areas of normal appearing skin but there is also considerable red area. My mistake in this case was in using mild pressure for short periods of ten to fifteen seconds for fear of causing scar-formation. Am now using moderately firm pressure for thirty to thirty-five seconds.

CASE 2. S. P., April, 1910. Age, twenty-eight years. Port-wine mark behind left ear, and extending down on

to neck over an irregular area size of the palm of the hand. Treated for a year with radium with no appreciable improvement. After four applications over period of four months there was a wonderful improvement. There is now a very little red area left behind the ear, and it is expected that this will soon be replaced by white skin.

### WARTS.

A large number of warts, particularly on the face, lips and scalp, have been treated with success.

#### CHLOASMA.

Case 1. M. C., October, 1909. Age, fourteen months. Since birth has had an area of very brown chloasma on left cheek 2 in. long by 1½ in. broad. Has had several applications over area at different times with varying amounts of pressure. At present the only remaining trace is a slight redness of the skin which is gradually fading out.

Case 2. D. W., June, 1909. Age, five years. Since birth has had a light brown area of chloasma extending irregularly across the right cheek from the ear to the middle of the upper lip. Liquid air applied to three portions of the area for ten seconds each. The mother reported that each area treated lost its brown color in about one week. Redness of the skin remained two months. In December, 1909, the remaining portions of the area were treated with one application each. The result has been perfect. Other cases of the same lesion of smaller extent have done equally well.

#### XANTHOMA.

Two cases of xanthoma have been entirely cured. In one, the process was on the side of the nose where it was being constantly irritated by eyeglasses.

Of perhaps more interest to the practitioner are the cases of the less benign new-growths, of which only a few descriptive cases will be cited.

#### EPITHELIOMA.

Case 1. W. H., March, 1910. Age, fifty-four years. Has had a growth in the skin over the bridge of the nose four to six months. Started as a small scaly "pimple." Has grown steadily ever since. Is now a hard nodule ½ in. in diameter with a depressed center covered with a crust, and indurated white edges. After three applications of twenty seconds each over period of one month, the lesion was entirely healed, leaving a small white scar. There has been no recurrence to date.

Case 2. S. M., May, 1909. Age, seventy-two years. Has had a growth just above right ear three to four months. There is a depressed center covered with a crust, with indurated edges. The area is 1 in. long by ½ in. wide. Two applications of twenty seconds each, repeated the next day, caused the disappearence of the lesion, and it has not yet recurred.

Case 3. A. S., December, 1909. Age, eighty years. Has had a growth on the right side of the nose for the past twelve years. Has grown no larger in the past two years. There is a button-like appearance, with heaping up of the edges and an ulcerated center. Liquid air applied in December and again in March, 1910. Lesion healed promptly with small white scar. No recurrence to date.

Case 4. G. L., February, 1909. Age, fifty-four years. Operated in 1888 for epithelioma of left inner canthus, and again in 1895. In 1903 x-ray treatment for six months. Operated again in January, 1908. Since then has had x-ray treatment twice a week with no especial benefit. Liquid air was applied to several portions of the new growth about the inner canthus at intervals of two weeks. Each area touched promptly healed. On March 31 it was noticed that there was a considerable extension on to the eyeball. Applications were made to the sclerotic conjunctiva on the advice of Dr. H. B. Chandler and with the consent of the patient. There was no especial pain, nor was there any other ill-effect. Two weeks later the portion thus treated was apparently healed. In May of the same year a small area internal to the eye on the lachrymal bone was treated. During the summer there was extension of the process internal to and behind the eyeball, leading to subsequent enucleation. The interesting feature of this case is that there was no recurrence in the areas treated. If the case could have been so treated in the beginning it is fair to assume that the spread of the disease might have been checked.

Case 5. E. W., January, 1910. Age, sixty years. Father and brother both had epitheliomata on their faces. This patient has had an epithelioma growing on the right cheek, midway between the eye and ear, for past twenty years. Area is about ¾ in. by ½ in. Another smaller area is situated just in front of the right ear, and there are two small areas about ¼ in. in diameter below this. The whole area over the zygomatic process feels nodular beneath the skin. The various areas were treated four times at intervals of two weeks, and healed readily. The patient, who is captain of of a sailing-vessel, came back recently with recurrences in the two larger areas. There were no glands to be felt in the neck. He was unable to remain in the city, and left before he could be treated. In this case radical excision of the epitheliomatous areas would have been impossible without extensive skin-grafting, owing to the tightness and adherence of the skin over the zygomatic process. Any operative procedure would have involved practically the whole side of the face.

Case 6. C. B., November, 1909. Age, fifty years. Has had a superficial epithelioma on the left cheek just below the eyelid. The center is slightly ulcerated, with surrounding induration. After two applications, two weeks apart, the lesion healed with no appreciable scar. There has been no recurrence up to date.

Two other cases of epithelioma on the cheek and nose, after remaining healed a year, have shown recurrences the size of a pinhead which have immediately yielded to treatment. Other cases have been treated so recently as to be of no value in this report. Compared with results after excision and other forms of treatment, and in consideration of the comparative painlessness and prompt healing of this method of treatment, it is quite certain that we have in it a valuable curative agent.

#### LUPUS ERYTHEMATOSUS.

Case 1. E. W., March, 1909. Age, thirty-two years. Has had a large number of areas of lupus for several years on the forehead and both cheeks. Treated in many ways at various hospitals with practically no relief. At different times the areas were treated by me with liquid air, and all of them promptly healed. During my absence in the summer several new areas appeared, and were treated at one of our hospitals with carbon dioxide snow. She reported in the fall that the process was painful and slow, and not very suc-

cessful. She afterwards moved away and has been lost track of since.

Another interesting case may well be reported here. F. Y., October, 1909. Age, thirty-nine years. Has been under treatment some time for tuberculosis of the bones of the nose. For several months has had a swelling in the right cheek near the nose which almost constantly discharges pus or serum through a small opening. There is a great deal of induration and redness with almost no pain. After several applications of liquid air there was a complete cessation of the discharge, and the induration practically disappeared. The effect of the liquid air in stimulating the sluggish tissues in this case suggests its possible value in indolent ulcers and other slowly healing processes.

In view of the results shown above it must be admitted that liquid air is of the greatest possible service in many affections. The painlessness of its application, due to its action as a local anesthetic, the ease and certainty with which it may be administered, after a proper amount of experience, make it a most welcome advance in our methods of treatment.

## Reports of Societies.

### AMERICAN MEDICAL ASSOCIATION.

SEVENTH ANNUAL CONFERENCE ON MEDICAL EDUCATION, HELD AT CHICAGO, ILL., MARCH 1, 1911.

THE chairman, DR. ARTHUR DEAN BEVAN, presiding.

The chairman, in calling the conference to order, said, first, that medicine was to-day a science just as chemistry was a science and physics was a science. The art of medicine to-day rested as firmly upon a scientific basis as did the practical application of chemistry and engineering, and as there could be but one science in chemistry, so from now on there could be but one science of medicine. The fads and pathies that formerly existed under the old empirical practice of medicine became impossible in the light of modern scientific medicine.

A thorough training in the sciences upon which medicine was based was essential in the modern medical curriculum, and a thorough familiarity with disease processes in the living patient must be mastered before the student was permitted to begin independent practice.

First, after graduating from high school at least one year of training in physics, chemistry and biology; two years in the science of anatomy, physics, pharmacology and pathology; two years in the study of medicine, surgery and obstetrics and the specialties, with the opportunity of studying those subjects in the dispensary and hospital, and, lastly, a year's practical training as an interne in a hospital in which the student was a part of the medical machine which was responsible for the proper care of the patients.

#### PROGRESS AND NEEDS IN MEDICAL EDUCATION.

DR. N. P. COLWELL, Chicago, secretary of the Council, presented a report on this subject and stated that since 1904 there had been a positive decrease in the number of colleges until now the number had been reduced to 129. Of the 44 colleges closed since 1907, 20 colleges were closed outright and 24 by merging with others. Of the 20 which became extinct, 16 had been graded in Class C by the Council on Medical Education.

Since 1904 there had also been a decided improvement in the standards of admission. Until 1904 only three, or 1.9%, of all medical colleges were requiring for admission more than a high school education, but now 41, or 31.8% (nearly one third), of all colleges were requiring for admission one or more years of collegiate work; and the teaching of medicine as a whole had been placed more largely upon a university basis.

He referred to other improvements, the improvements that were still needed, and said that the educational safeguards were still faulty. The low-standard colleges referred to could exist only in states where the laws regulating the practice of medicine were inadequate or were not enforced. The solution of many of the problems of medical education rested in the hands of the state licensing boards and doubtless would be solved by them if they were given a fair chance. As a rule, the board was too closely connected with politics, and in some states the members were appointed largely for political reasons and were liable to be changed with every turn of politics.

He said there should be one portal to the practice of medicine. Not only should there be but one board in each state, but there should be a single educational standard fixed with which every applicant for a license to treat the sick by whatever means or methods should comply.

#### ENTRANCE EXAMINATIONS.

DR. THOMAS S. FISKE, of New York City, enumerated the following manifest advantages of the examinations held by the college entrance examination board: First, that they were uniform in subject matter. Second, that they were uniformly administered. Third, that they were held at many points to meet the convenience of students at one and the same time. Fourth, that they represented the co-operative effort of a group of colleges, no one of which thereby surrendered its individuality. Fifth, that they represented the co-operation of colleges and secondary schools in respect to a matter of vital importance to both. Sixth, that by reason of their uniformity they aided greatly the work of the secondary schools. Seventh, that they tended to effect a marked saving of time, money and effort in administering college admission requirements.

#### FIVE-YEAR MEDICAL COURSE.

DR. J. G. ADAMI, McGill University, Montreal, stated that of the five-year course in medicine now in operation in the leading Canadian schools it was not deemed essential that all the medical schools of the continent should adopt such a course. There might be other medical schools having a similar environment, however, which might obtain the best results educationally by establishing a similar course. Briefly, the objects in the development of the curriculum at McGill had been, first, to give a sound course in the preliminary science subjects; second, to make the courses from the first to the fifth year as practical as possible; third, to observe a natural sequence in the various courses; and, fourth, to give the maximum hospital instruction with the freest employment in the wards and of bedside instruction.

#### EQUIPMENT AND INSTRUCTION OF THE LABORATORY YEARS.

DR. E. P. LYON, of St. Louis, stated that the scientific instruction must be in the hands of professional scientists, not practitioners of medicine. They must be provided with proper laboratories for teaching and research with equipment, materials, libraries and as-

sistants. Anything less than this provision was to disregard the model which the school was trying to realize, namely, the good doctor. The laboratory work should be conducted by the professors and not by cheap assistants. If the right men were chosen for heads of departments, the choice of specific equipment might be left to them. The State Board would do well to insist that the colleges have trained instructors rather than publish lists of required equipment which might or might not be used. The three powers of good observation, experimentation and judgment were necessary for the technical work of the physician. But on account of his intimate relation to the people he needed many other physiological traits which might be summed up as character. The medical school could do little by precept, but much by example. The medical teachers should be men of character and culture.

INSTRUCTION AND EQUIPMENT OF THE CLINICAL YEARS.

Dr. George Blumer, Yale University, stated that the problem of teaching in clinical years was a threefold one: Training in the fundamental principles of medicine, surgery and obstetrics; practical training in physical and clinical diagnosis; and surgical technic. There was opportunity to apply the principles of technic by actual contact with patients. He made a comparison of clinical and didactic teaching as methods of imparting fundamental training. He pointed out the advantages and disadvantages, and said the proportion of such was determined by local conditions. There was a tendency to overemphasize didactic teaching. Technical training in clinical and physical diagnosis must be by laboratory methods. Didactic methods were out of place. He spoke of the advantages of the use of living animals in teaching surgical technic. Contact of students with individual patients was the keynote of the fourth-year instruction. A system of clinical clerks was desirable. Students should do most of the work in clinics.

He referred to the equipment necessary and spoke of laboratories with microscopic and necessary apparatus to teach students. The dispensary especially should be equipped for teaching with abundant material. The hospital especially should be equipped for teaching under competent medical school control. The greatest problem at present was lack of proper endowment, namely, properly paid and trained men in clinical years. There was a lack of absolute control of hospitals by medical schools.

SUBJECTS INCLUDED IN THE TWO YEARS OF COLLEGE WORK REQUIRED FOR ADMISSION TO MEDICAL COLLEGES.

Dr. Charles R. Bardeen, Madison, Wis., said that during the two years of college work required by the majority of medical colleges which could afford to maintain high preliminary standards, about half the time should be devoted to physics, chemistry, biology and English. The other half of the time should be divided between the study of foreign languages and one or more non-technical studies, such as art, history, economics, civics, mathematics and philosophy. The aim of this preliminary college work should be to produce breadth of view as well as to give some understanding of scientific knowledge and methods.

STATE LICENSE EXAMINATION.

Dr. Horace G. Norton, New Jersey, contributed a paper on this subject. The primary object of the examination was to determine whether the applicant had a competent practical knowledge of the science of medicine, and that he was not giving quiz-compend answers. Every experienced examiner could, he thought, distinguish compend answers from answers given from a full understanding of the subject. The examination of the student included his academic qualifications, and the reliability of the medical school from which he graduated. He thought that written examinations were good so far as they went, but they must be supplemented by other and practical tests. In his state the present law directed a written examination. He hoped this winter that a better medical law would be passed allowing the instruction of a practical examination. He had no personal knowledge of examinations in other countries, but would be glad to hear from those who had. What practical examinations should be required without too much trouble and expense? He was sure that the bedside examination in a hospital was impractical and unnecessary because of the time consumed. He did believe, however, that refraction, blood examination, urinary examination, recognition of pathological and bacterial slides, a showing of ability to use a microscope and the possible detection of heart and lung lesions and chemical reactions were practical. He then described the best method of preventing impersonation.

INTERSTATE RECIPROCITY.

Dr. W. T. Gott, Indianapolis, Ind., stated that in recognition of a strong demand in the profession some states entered into reciprocal agreements as early as 1901, and that at the present time the majority of states had such agreements with certain other states. Reciprocity in medical licensure, if conscientiously administered, had a favorable influence on educational standards. State practice acts were not apt to be weakened or the standards lowered, since that would endanger the reciprocal relations with other states. Medical colleges also were urged to keep their standards high, since their students were thereby made eligible to registration through reciprocity in a larger number of states.

As long as cults in the healing art existed, according to the speaker's judgment, it was a serious mistake to provide for each a separate board of medical examiners. The administration of such boards was consciously or unconsciously influenced by biased sympathies and unnecessary temptation was put in the hands of such boards to be lax in passing on the credentials of applicants of their own system of practice. The speaker further believed that credentials issued by a board composed entirely of representatives of one school or system of practice should not be acceptable for a certificate through reciprocity, and that such a ruling would have a salutary effect in upholding the standard of educational qualifications throughout the country.

Dr. Frank B. Hiller, Jefferson City, Mo., read a paper entitled "Valuation of Credentials."

Dr. James B. Herrick, of Chicago, followed with a paper entitled "Educational Functions of Hospitals."

At the joint conference on Medical Practice Acts, several papers were read bearing on medical practice acts and the public, the attitude of the judiciary in the enforcement of medical practice acts, and what should be the attitude of the state toward the practice of medicine. The subjects of the regulation of the practice of medicine for the public good, and the administrative duties of the State Boards of Medical Examiners were discussed.

At the Seventh Annual Conference on Medical Legislation the committee on resolutions submitted the following report, which was unanimously adopted:

*Whereas*, the Committee on Carroll Memorial has completed its work in a manner highly satisfactory to all concerned,

*Resolved*, that the final report of the committee be accepted and the committee discharged; and be it further

*Resolved*, that the committee recommends that the cordial thanks of the Conference and of the Association be extended to Major Ireland and his committee for the efficient manner in which they have accomplished their work.

*Resolved*, that the thanks of the Conference be extended to Drs. Halsey, Gay and Bristow for their individual efforts in the consideration of medical expert testimony and that this committee be discharged; and be it further

*Resolved*, that the Council on Health and Public Instruction be requested to establish a standing committee to give this matter thorough consideration and if possible to confer with a committee of the American Bar Association.

*Resolved*, that the Seventh Annual Conference of the American Medical Association on Medical Education and Medical Legislation deplores the action of Columbia University of New York in establishing a course of study in optometry, for the reason that opticians have never succeeded in founding an official school of optics or optometry, but have relied on the recognition or legalization of the word "optometry" to make them a profession, and for the further reason that the existence of such course at Columbia University has this year been used in many states as the chief argument for the further enactment of optometry laws, which are designed to permit opticians to practice medicine in a limited degree; and be it further

*Resolved*, that a copy of these resolutions be transmitted by the secretary of this Conference to the president of Columbia University of New York.

*Resolved*, that this Conference reaffirm its endorsement of the model bill on vital statistics and express its appreciation of the interest shown by Hon E. D. Durand, Director of the Census, and by Dr. Cressy L. Wilbur, Chief of the Division of Vital Statistics, in promoting the adoption of uniform vital statistic laws in the various states, and that the secretary be instructed to furnish a copy of these resolutions to the above-mentioned gentlemen.

## PHILADELPHIA COUNTY MEDICAL SOCIETY.

MEETING OF WEDNESDAY, DEC. 28, 1910.

The President, DR. HENRY LEFFMANN, in the chair.

SYMPOSIUM ON PNEUMONIA.

DR. W. M. L. COPLIN spoke upon:

### THE PATHOLOGY AND MORBID ANATOMY.

### SYMPTOMS AND COMPLICATIONS OF LOBAR PNEUMONIA.

DR. JAMES M. ANDERS: While the mode of onset is characteristic in about 80% of the cases, about 20% begin insidiously. The latter often pursue a protracted course, with slow defervescence and are apt to show complications and sequelæ. Defervescence by lysis is more commonly observed at present than formerly, but they are unattended by a decided fall in the leucocyte count, while the reverse is true of the actual crisis. A high pulse-rate implies danger in pneumonia. Leucocytosis may be slight or absent in cases in which the struggle for life is lost. I have never observed leukopenia, but this may occur; and leucocytosis is also absent in cases in which the scene is dominated by a prior infection, e. g., typhoid fever and certain other conditions. It is important that an examination of the lungs be made in cases of mania potu in which fever is present, since all other characteristic features may be in abeyance. The adhesive, rusty-colored sputum is a characteristic feature, but it is sometimes absent in the pneumonias occurring in the aged, in drunkards and in those showing marked toxemia. The physical signs yield evidence of great diagnostic importance. The value of systematic physical examination of the thorax with a view to detecting consolidation when present in suspicious cases is of the highest importance in subjects of emphysema, and in the aged, the acute infections, as well as in the commoner chronic diseases when fever develops. Attention is directed to certain signs which rarely arise in the opposite or uninvolved lung, such as impaired percussion-resonance, râles over the base, and to the fact that these are readily confused with actual consolidation. If practicable, blood cultures should be undertaken in dubious cases. Pleurisy with more or less effusion complicates pneumonia in about 50%. In at least 20%, heart complications are present. Pleural effusion of moderate degree is extremely apt to be overlooked during life. Needling is essential in doubtful cases and also to distinguish between serum and pus. The special bacterial agent should always be isolated. Among the commoner complications of pneumonia is empyema. In encapsulated empyema following pneumonia, a positive diagnosis is sometimes extremely difficult. Other means failing to prove the presence of pus, an exploratory operation should be done. In consequence of the toxemia or pneumonic septicemia, cardiac exhaustion may ensue without any marked histologic changes in either of the valves or the myocardium. Acute endocarditis is present in about 10% of the cases of pneumonia. It differs from other varieties: (1) in that three fourths of the cases are ulcerative; (2) that women show a higher incidence than men in the proportion of 2 to 1; (3) that the aortic cusps are more commonly involved than the mitral. Pneumococcus endocarditis generally prevents the occurrence of the crisis. Pericarditis is a more frequent complication than endocarditis. Meningitis may be associated with endocarditis or occur independently as a complication, but this is comparatively rare. It can be diagnosed only by the presence of such features as bradycardia, paralyses and neuroretinitis, or, in the absence of definite symptoms, by lumbar puncture.

We are indebted to Norris for the observation that acute nephritis probably occurs in about 7% of pneumonic infections. The writer has elsewhere shown that chronic nephritis is frequently found at autopsies in cases of pneumonia (70% of the cases at the Philadelphia Hospital), so that may be regarded as one of the commonest foregoing diseases.

### PNEUMONIA: DIAGNOSIS.

DR. AUGUSTUS A. ESHNER: In the majority of cases the diagnosis of pneumonia is easy. With a history of exposure to cold, followed by chill, fever, pain in the chest, dyspnea, rapid, shallow breathing, irritative cough, viscid mucoid hemorrhagic sputum, labial herpes, pneumonia will suggest itself, and the diagnosis will be confirmed by physical examination. Difficulty in the recognition of pneumonia will arise principally in atypical cases. Error is to be avoided by constant vigilance, with frequent physical exploration. Among the disorders from which pneumonia requires to be differentiated are acute pleurisy, pulmonary tuberculosis, bronchopneumonia, congestion of the lungs, infarction, abscess, gangrene, bronchiectasis, actinomycosis, syphilis, malignant disease, pericardial effusion, meningitis, typhoid fever.

SURGICAL COMPLICATIONS AND THEIR TREATMENT.

DR. CHARLES F. NASSAU: Pneumonia is not wholly a medical disease, as is generally believed. With enormous effusion removal by operation is the only proper course. Careful attention should be given to the cardiac condition. In a true empyema the treatment is clear: Incision, with or without resection of the rib, and drainage. Abscess or gangrene of the lung is one of the most difficult propositions confronting the medical man and surgeon. The treatment of either consists in rib resection and the insertion of a drainage tube. There is a sentiment against tapping suppurative collections in the pericardium, and I believe it is very much safer to make a small rib resection, expose the pericardium, when a needle can be introduced with comparative safety. In sixteen years I have seen very few cases of arthritis complicating pneumonia. It affects chiefly the knee and occurs most frequently in children. Absolute diagnosis rests solely upon bacteriological examination of the joint fluid. When the pain in pneumonia is referred to the abdomen, the pain and tenderness may be as pronounced as in acute abdominal disease. Diagnosis is so difficult that laparotomy may be done.

MEDICAL TREATMENT OF PNEUMONIA.

ARTHUR NEWLIN, M.D.: The mortality of pneumonia is maintained at 20% or over, death or recovery occurring usually, not so much as the result of inefficient or successful treatment, but in direct proportion to the individual's innate power to combat his infection. On account of the constant presence of pneumococcus in the normal individual it behooves us to avoid those things that reduce our natural resisting powers. Pneumonia patients should be isolated when possible. Two chief ends to be sought are the preservation of the patient's bodily strength and the maintenance of his personal comfort. Local measures, such as cupping or strapping, are used for the control of pain. The use of baths is not advised in adults, but hot baths in children are frequently of value. Dyspnea and cyanosis are better controlled by cold air than by any other means. Cold-air treatment has met with very good results. Milk remains the staple diet for pneumonia patients. The intestinal tract should be cleansed by calomel and salines. Such expectorants as creosote and ammonium chloride are rarely necessary; respiratory stimulants, such as strychnine, atropine and aromatic spirits of ammonia, are useful. They should be administered as occasion indicates. Phlebotomy has its use when the consolidated lung offers a mechanical obstruction to the pulmonary circulation. The circulatory system offers the best opportunity for the display of judgment in the administration of drugs. For the cardiac weakness which results from fatigue and toxemia, such stimulants as strychnine, digitalis, aromatic spirits of ammonia, caffeine, atropine and camphor may be used. Of these, strychnine and camphor are probably the best. Alcohol and digitalis are sometimes of use. Although there are objections to alcohol, yet in the aged and to those addicted to the use of the drug it may be used with benefit. Digitalis is better given hypodermically, and of its preparations preference is given to the fat-free standardized tincture. For lowered blood pressure, rapid pulse and tympanites, adrenalin, hypodermically, after the method of Gibson and Forcheimer, may be employed; its dose is 1 ccm. of a 1:1,000 solution.

Strophanthin is a drug that has come into vogue in the past two years. It is a powerful cardiac stimulant and is given intravenously in milligram doses. Such a dose shall not be repeated within twenty-four hours. Vaccine and serum therapy has as yet not proved to be efficacious in the treatment of pneumonia. The treatment should be one of conservatism, relying upon fresh air, various local measures and the ability to give the right drug at the right moment with the avoidance of routine administration.

DISCUSSION.

DR. HENRY D. JUMP: Blood pressure estimated in the prognosis and treatment of pneumonia I believe to be of far more value than the estimation of the respiratory rate. As has been pointed out, there is at a certain time in the toxic condition of pneumonia a lowered blood pressure accompanied by an accelerated pulse which indicates a grave prognosis. This has seemed to me to offer a very distinct indication for therapeutic measures, and I am surprised that the observation has not attracted more attention in the treatment of pneumonia. Associated with this lowered tension and accelerated pulse we have, as a rule, a tympanites due to vasomotor paresis of vessels of the splanchnic. If this vasomotor paresis goes on to the greatest extent, the body becomes bled into its own vessels and active interference is called for, as pointed out by Dr. Hare.

DR. J. NORMAN HENRY: I have had satisfactory results with the use of quinine administered hypodermatically and the administration of salt solution by hypodermoclysis. I have only recently tabulated my results and have not yet published them. In sixty-five cases of croupous pneumonia in the Pennsylvania Hospital I have had ten deaths, and some of these cases were moribund at the time the treatment was begun.

DR. HOBART A. HARE: I do not think Dr. Henry gives his treatment a fair show when he includes the cases that were moribund. The remarks upon these cases emphasize the important point than in the vast majority of instances pneumonia is not a primary frank disease. To ascertain the value of any line of treatment in pneumonia we would have to have statistics covering hundreds of cases and divide them up into innumerable groups. The matter of the lowered arterial pressure and accelerated pulse-rate is one of the greatest importance in that it tells you not only that danger is pending, but tells you far ahead of the time.

## NATIONAL CONFEDERATION OF STATE MEDICAL EXAMINING AND LICENSING BOARDS.

TWENTY-FIRST ANNUAL CONVENTION, HELD AT THE CONGRESS HOTEL, CHICAGO, ILL., FEB. 28, 1911.

THE PRESIDENT, DR. JOSEPH C. GUERNSEY, Philadelphia in the chair.

An address of welcome was delivered by DR. GEORGE W. WEBSTER, Chicago, which was responded to by DR. LEE H. SMITH, Buffalo.

PRESIDENT GUERNSEY delivered an address on medical licensure.

FLEXNER REPORT.

DR. W. J. MEANS, chairman, Columbus, Ohio, presented the report of the committee on the recommendations contained in Mr. Flexner's paper of last year, and stated that they concerned subjects which had been frequently presented and discussed at meetings of the National Confederation as well as of the Association of American Medical Colleges and of the Council on Medical Education. The committee recom-

mended that most careful consideration be given to all of the suggestions made, and that the three special recommendations, namely, regarding preliminary education, the refusal to recognize poorly equipped schools, and practical examinations, be adopted. The committee further recommended that a special vote of thanks be extended to Mr. Flexner for his most excellent paper.

The report was adopted.

STATE CONTROL OF MEDICAL COLLEGES.

DR. CHARLES WILLIAM DABNEY, president University of Cincinnati, said the vital interests of the general public in medical education furnished the strongest argument for the public support and control of medical colleges. The privately controlled colleges had generally lost sight of this and considered the interests of the profession and of the student the chief thing. In no other way did education as a whole touch the citizen more vitally than in the character of the medical training given in the colleges. The interest of the public in the kind of education given practitioners of medicine was the chief justification of public control of these institutions.

MR. ABRAHAM FLEXNER, New York City, discussed the subject of the duty of the state in the control of medical colleges.

HON. CHARLES ALLING, JR., Chicago, spoke of state support and control of medical education, and said that if the courts will sustain as a requirement for an examination a diploma from an institution of the standard raised by the Association of American Medical Colleges, they should for the same reason sustain a law providing that the degree of M.D. shall be given only by medical colleges in good standing with the State Board of Medical Registration and Examination, an official body created by and acting for the state to secure good medical service for all the people.

DR. ARTHUR DEAN BEVAN, Chicago, discussed the advantages to medical colleges of state control, and said that proper state control would mean a great deal and be of great advantage to the medical college which was doing good work and developing along scientific lines.

He believed that if every state board represented in the Confederation would attempt to get the profession of its own state back of it and made proper state control effective, that within five years American medicine could be placed in a position, with the exception of a very few states, where we could say that the American medical student was obtaining the proper medical education; that he had had a proper preliminary and medical education and some practical hospital experience before he was allowed to practice medicine.

SOME EVILS IN THE PRESENT SYSTEM OF MEDICAL EDUCATION.

DR. F. C. WAITE, Cleveland, Ohio, said the evils of over-production of graduates was self-evident. First, the field being overstocked, the average income and adequate living are reduced. Second, from this the result must be that the more able members of following generations will shun the profession and its recruits must come from the mediocre. The general tone of the profession will thereby diminish. Third, the average lack of income from reputable and ethical practice in the profession would lead many into quackery and thereby reduce the dignity and respectableness of the profession, and would divert the tendencies of able young men from the profession.

The following papers were also read and discussed: "Would it Add to the Efficiency of Medical Education to have All Teachers Receive a Compensation Commensurate with their Labors and have a Larger Number Devote their Entire Time to Teaching than now Obtains, and Could this be Accomplished if Aid were Rendered by the State?" by Dr. Frank Winders, Columbus, Ohio; "Could Examining and Licensing Boards Enforce the Laws Regulating the Practice of Medicine and the Requirements of the Boards More Efficiently, if Medical Education were under State Control?" by Dr. Edward Cranch, Erie, Pa.; "If Medical Colleges were under State Control, would the Medical Profession be More Uniformly and Efficiently Educated and Trained than by the Present System?" by Dr. Royal S. Copeland, New York City; "Some Thoughts on the Supervision of Medical Colleges and the Conducting of State Examinations," by Dr. James A. Egan, Springfield, Ill.

The following officers were elected: President, Dr. Charles A. Tuttle, New Haven, Conn.; First Vice-President, Dr. James A. Egan, Springfield, Ill.; Second Vice-President, Dr. A. B. Brown, New Orleans, La.; Secretary-Treasurer, Dr. George H. Matson, Columbus, Ohio; Executive Council: Dr. N. R. Coleman, Columbus, Ohio, chairman; Dr. Charles H. Cook, Natick, Mass.; Dr. Joseph C. Guernsey, Philadelphia, Pa.; Dr. W. Scott Nay, Underhill, Vt.; Dr. James A. Duncan, Toledo, Ohio.

Chicago was selected as the place for holding the next annual meeting of the Confederation.

## Book Review.

*Urgent Surgery.* By FELIX LEJARS, Professeur Agrégé à la Faculté de Médecine de Paris; Chirurgien de l'Hôpital Saint Antoine; Membre de la Société de Chirurgie. Translated from the sixth French edition by WILLIAM S. DICKIE, F.R.C.S., Surgeon North Riding Infirmary, Middlesbrough; Consulting Surgeon, Middlesbrough Union Infirmary; Consulting Surgeon, Eston Hospital. With 20 full-page plates and 994 illustrations, of which 602 are are drawn by DR. E. DALEINE and A. LEUBA, and 217 are from original photographs. Vol. II. The Genito-Urinary Organs, the Rectum and Anus, the Strangulated Hernias, the Extremities. New York: William Wood & Co. 1910.

Volume II of Lejars' important work deals with the genito-urinary organs, the rectum and anus, strangulated hernia, the extremities and other important topics which he has not discussed in Volume I. Our remarks some months ago on the value of Volume I apply equally to Volume II. The book is truly a discourse on operative surgery mainly, and the topics are admirably presented. The excellence of the text and illustrations consists mainly in the brevity of the writing, the admirable selection of methods chosen and the illuminating nature of the cases. It is a forceful and satisfying production. An extended criticism does not seem necessary here, for, beyond the method of presentation, there is little in the work that is new. The two volumes form together a book of reference for the busy general surgeon, and add one more to our already large collection of similar works.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, MARCH 16, 1911

*A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.*

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.*

*All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.*

*Remittance should be made by money order, draft or registered letter payable to*

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

## REPORT OF THE MASSACHUSETTS STATE BOARD OF HEALTH FOR 1909.

The forty-first annual report of the State Board of Health of Massachusetts for the year ended Nov. 30, 1909, has but just made its appearance, owing to delay in the printer's office. It is a bulky volume and contains a large amount of interesting and detailed information. The year which it covers represents essentially the first year of Dr. Mark W. Richardson's secretaryship of the board.

The introductory general report comments on the principal activities of the board during 1909, on the slaughtering of neat cattle, sheep and swine, on its investigation relative to the treatment of rabies, on its work with reference to water supply and sewerage, on its supervision of the business of plumbing, on its inspection of foods and drugs, and on outbreaks of infectious disease. Many of these topics are more extensively treated by special papers in the supplement which constitutes the greater part of the volume. Of particular interest is the report by Dr. Lovett on "The Occurrence of Infantile Paralysis in Massachusetts in 1909," which was published in the issue of the Journal for July 14, 1910. Dr. Gregg's report on the "Origin and Prevalence of Typhoid Fever in Boston in the Year 1909" concludes with the significant recommendation that "all persons who are accustomed or forced to travel into other parts of the country, especially to the South and to Canada, or into rural districts, where the chances of getting contaminated water, milk, shellfish or other articles of diet are many, and almost impossible to guard against, and all physicians, nurses, ward tenders and hospital employees, should receive prophylactic [antityphoid] inoculation." The statistical summaries of disease and mortality present comparative general reviews of the vital statistics of the state for 1908 and 1909. The total death-rate of Massachusetts for the former year was 16.55 per 1,000; for the latter, 16.16. The total number of deaths from consumption in 1907 was 4,771; in 1908, 4,445; in 1909, 4,393. The typhoid death-rate in this state per 10,000 inhabitants was in 1909 only 1.23, but even this is a figure which in the future should be still further reduced.

The report of the board and its several departments not only describes the extent and variety of the important work accomplished, but is itself a valuable contribution to medical literature.

## THE STATUS OF ANTI-VIVISECTION.

The occurrence this week in Boston of so-called anti-vivisection meetings and of an anti-vivisection exhibit at Tremont Temple calls renewed attention to the persistent activity and zeal of certain misguided though well-intentioned persons in their efforts to hamper and if possible check the employment of animal experimentation in medical research. This demonstration immediately follows one of a similar nature in New York, to which we referred in notes in the two preceding issues of the Journal, and which was attended by an attempt to secure the passage at Albany of anti-vivisection legislation. It is of interest to examine some of the methods by which such campaigns are conducted, even though their nature and the qualifications of those engaged in them do not rouse serious apprehension of their success.

The anti-vivisection exhibit, announced as having "accomplished wonders for the cause wherever held," reflects with approximate accuracy the mental state of its promoters, being an admixture of misapprehension, misrepresentation and hyperbolic emotionalism. It is arranged and intended as a chamber of horrors, and is really a very distressing place for any one of good feelings to visit. It does not in the least resemble the so-called "halls of agony" of modern medical schools. The displays in this exhibit seem to fall under three classes. First, there are the pictures and models representing an animal, usually a dog, always unanesthetized, gagged and stretched writhing on a rack of inquisitorial design, extensively mutilated, and undergoing further torture at the hands of a satanic professor to the delight of a benchful of

degenerate medical students. "Isn't it awful?" said one shocked and kindly old gentlemen, contemplating the scene; "you wouldn't think they could do such things, but —" in a burst of inference and conviction — "the doctors are all like that." Such an instance and remark illustrate precisely the really criminal and dangerous method by which the finest emotions of the mind are played upon, exploited and perverted to serve the purpose of a particular cause. The imaginations of the anti-vivisectionists are far more diabolic than those of the most inhuman experimenter they depict. If half of all they conjure up were true, everybody would desire the restriction of animal experimentation. Their intellectual error lies in the misinterpretation of what they may have seen or read. An uninformed person might similarly construe surgical appliances and apparatus as instruments and engines of torture and depict the orthopedic ward of a hospital as a "hell chamber of atrocity."

To anti-vivisectionists the word "experiment" is equivalent to "malicious and cruel procedures on living creatures, devised ingeniously to inflict the maximum of pain," which is supposed to be equivalent to the maximum of pleasure for the inflictors. Indeed, they do not hesitate to aver that doctors purposely practice such procedures on their patients "for the fun of it," and as examples they quote liberally from medical articles, which happen to contain the word "experimental," and which as prejudiced laymen they naturally misconstrue. Placards bearing such quotations and insinuations constitute the second class of displays in this exhibit. A single example must suffice. In Vol. cxxxv of the JOURNAL, pages 132 and 156, Dr. A. H. Wentworth reported "Some Experimental Work on Lumbar Puncture of the Subarachnoid Space." The anti-vivisectionist's version of this is, "Dr. Wentworth made forty-five vivisections, tapping the spinal canals of children, many of whom died!" Such is the interpretation put on some of the early work on one of our now common and beneficent means of diagnosis and treatment. Other similar misrepresentations are derived from sensational newspaper reports of scientific research or surgical procedure.

The third class of displays at the exhibit consists of pictures of those whose writings oppose, or are thought to indicate opposition to, animal vivisection; and of domestic animals performing heroic rescues of men and children or in circumstances of felicity as widely contrasted as possible with their depicted torments above described. This part of the exhibit was a geunine relief to any one who before the other cases has already "supp'd full of horrors."

Of the part played in this campaign by the much-heralded Dr. Snow, little need be said. In the published correspondence to which we referred in the issue of the JOURNAL for March 9, Dr. Ewing, of New York, has satisfactorily answered his statements and appraised his standing, as Dr. Keen, of Philadelphia, previously had done. In his lecture at Tremont Temple on March 13, he declared that "it has never been definitely proved that a germ is the cause of any disease; that wherever diphtheria antitoxin has been introduced, the mortality from diphtheria has risen; and that doctors who knew how could perfectly well cure the worst cases of diphtheria before the days of antitoxin." Such remarks are sufficient to indicate that Dr. Snow has never progressed beyond the views of fifty years ago. They would be insulting if they were not laughable. By the use of such assertions he has simply exposed his own cause, and, as Dr. Ewing has said, withdrawn himself "from the range of scientific criticism and the serious consideration of all sensible people."

The result of the present anti-vivisection demonstration in Boston should be to discredit rather than advance "the cause" with all except the untutored whose good emotions may be played on by the unjustifiable appeals made to them. The anti-vivisectionists are more to be pitied than feared, for they are genuinely deluded. Sometimes, however, such fanatics do succeed temporarily in blocking the course of human progress. They should, therefore, be watched by the medical profession, treated always with tolerance and courtesy, and answered with the unanswerable arguments of fact. For against scientific truth no fallacy or misrepresentation can ultimately prevail.

## POLIOMYELITIS IN THE UNITED STATES IN 1910.

A WEEKLY report of the United States Public Health and Marine-Hospital Service, published on March 3, contains an interesting table summarizing the cases and deaths of poliomyelitis reported in this country during the year 1910. The greatest number of each was in Pennsylvania, where there were 1,097 cases and 172 deaths. In Iowa there were 638 cases and 161 deaths; in Massachusetts, 588 cases. The number of deaths in Massachusetts is not given. Pre-

sumably these were the three states in which the epidemics of this disease were most severe, though it must be remembered that the incompleteness, unreliability or absence of statistics in some states prevents accurate comparison. Apparently the epidemic was most continuous in Iowa, for this is the only state from which cases and deaths were reported for every month of the year. The maximum number of cases in any month was 378 in September in Pennsylvania; the maximum number of deaths, 64, in the same month and the same state. The maximum number of cases in any month in the entire Union was 1,146 in September; the maximum number of deaths, 182, in August. The total number of cases and deaths of poliomyelitis in the United States during the calendar year was 5,093 and 825 respectively, a mortality of about 13.75%.

## DR. IRVING FISHER'S REPORT ON NATIONAL VITALITY.

In an editorial on "Inaccuracy of Vital Statistics in the United States," on page 167 of the issue of the JOURNAL for Feb. 2, we referred to an article by Mr. Lawrence Irwell, of Buffalo, criticising certain figures and statements in two recent papers by Professor Fisher printed in bulletins of the Committee of One Hundred on National Health. Mr. Irwell has now published, in the issue of *The Lancet-Clinic* for Feb. 18, a further "Examination of Prof. Irving Fisher's Report on National Vitality," in which he makes a more extended comparison of Fisher's statistics with those from other sources, and also devotes some attention to "problems connected with heredity" and to Christian Science. It is unfortunate that there seems a slight suggestion of personal animus in Mr. Irwell's paper, which impairs to some extent the effect of its conclusions. Many of its positions, nevertheless, seem well taken, for argument at any rate; and it illustrates, like his original article, "the uncertainties involved in vital statistics and their interpretation, and the extreme caution which should be observed in making or accepting any conclusions deduced from them."

## ANCIENT AND MODERN FOOD ADULTERATION.

In a recent address before the Boston Scientific Society, Mr. H. B. Smith, chief of the Boston Food and Drug Laboratory of the United States Department of Agriculture, is reported to have called attention to the extensive adulteration of cheap candy with arsenic, which is used as an ingredient of the shellac or varnish with which such candy is often coated. Some samples of this varnish, used in Boston, are said to have contained 0.13% of arsenic. Mr. Smith cited a number of other instances of violation of pure food and drug laws. The adulteration of food he declared to be as old as history. In Pliny's time, the Neapolitan bakers mixed white earth with their flour and then sold the bread by weight. Punishment of such malefactors was sometimes more rigorous than in our day. In Germany a medieval falsifier of Rhine wine was condemned to drink a gallon of his own vintage, from which he died. Since the passage of our own Food and Drugs Act, the Department of Agriculture has secured seven hundred and thirty convictions under its provisions, and though the practice of adulteration has been checked, it is not yet extinct. Perhaps it is a pity that such drastic punishments as that of the German wine-grower are no longer permissible.

## MEDICAL NOTES.

A MEDICAL DEGREE FOR EMPEROR WILLIAM. — Report from Berlin states that the University of Prague has recently conferred an honorary medical degree on the German emperor.

CHOLERA AT HONOLULU. — During the week ending March 11, 7 new cases and 6 deaths of Asiatic cholera were reported at Honolulu, making a total of 26 cases and 21 deaths since the outbreak of the epidemic there on Feb. 24.

FOOT AND MOUTH DISEASE IN ENGLAND. — It is reported from London that there has recently been an outbreak of foot and mouth disease among livestock in Surrey.

ENDOWMENT OF A CHAIR OF EUGENICS. — Report from London states that the late Sir Francis Galton bequeathed a sum equivalent to $225,000 for the establishment of a chair of eugenics at the University of London.

SOME MEDICAL PROVERBS. —In a recently published advertising medical almanac are several items that seem more than usually humorous. In a series of aphorisms and modified proverbs are the following:

"The patient must trust his doctor, but it is a poor rule that works both ways."

"It is significant that doctor and debtor have the same abbreviation — 'Dr.'"

"No man is a hero to his valet, and no woman an angel to her physician."

"It's an ill wind that blows the doctor much good."

A Somnarium in Touraine. — Report from Paris describes the recent establishment in Touraine of a somnarium, or institution for the treatment of the functional neuroses and psychoses by sleep. Its purpose is to afford an asylum of absolute quiet and rest to which patients may go for a period of temporary oblivion. The extent to which hypnotic drugs will be employed in this "cure" is not stated.

A Fourth State of Matter. — It is reported from London that in a recent lecture before the Royal Institution Professor Bragg, of Leeds University, advanced the hypothesis that there may be a fourth state of matter, in which the corpuscles or electrons, which are equivalent to the $\beta$-rays of radium, behave like the molecules of gases. By this theory may possibly be explained certain phenomena of light and other forms of radiation or emanation.

Public Health and Commercial Prosperity. — In an address on March 11 before the Southern Commercial Congress, Surgeon-General Walter Wyman, of the United States Public Health and Marine-Hospital Service, emphasized the importance, in the economic and commercial development of any community, of securing favorable hygienic and sanitary conditions of life for the people. Preventive medicine must henceforth go hand in hand with all the enterprises of civilization. In the South, Dr. Wyman pointed out that the prevalence of typhoid fever, malaria and uncinariasis is a considerable obstacle to economic progress.

Field Practice for the Army Medical Corps. — Modern military maneuvers afford an opportunity not only for the trial of new engines of war, but for the training and practice in the field of the army medical corps. In connection with the present mobilization of United States troops along the Mexican frontier, it is announced that there will be established two base hospitals, four ambulance hospitals and fourteen regimental hospitals. In addition, it is reported that the hospital ship *Solace* will be ordered to co-operate with the land forces.

Medical Discoveries Resulting from the Spanish War. — In a recent speech at Washington, D. C., President Taft is reported to have said that "the discoveries made by American physicians, and particularly army surgeons, during and as a result of the Spanish War are alone enough to justify that war." Whether or no this be undue praise for the profession, it is true that the war and its consequences gave occasion and opportunity that might not otherwise have so soon occurred for the demonstration of certain facts in scientific medicine and for their successful application to problems of hygiene and medical prophylaxis. The beneficent results of war are generally those which are least expected.

Progress of the Plague in China. — Reports from China state that, owing to the rigorous medical and sanitary measures adopted, there has been a marked decrease in the number of cases of bubonic plague at Pekin, Tientsin, Tungcho and in the northern provinces of that country. At Pao-ting-fu there were reported 28 cases and 26 deaths. In southern China there has been an outbreak of the disease at Siokhe, a village west of the Lung Kiang River and fifty miles inland from Amoy. At Amoy, during the fortnight ending March 11, there are said to have been 8 deaths from smallpox and 8 from bubonic plague.

Amendment to the Owen Bill. — A recently issued bulletin (No. 49) of the Committee of One Hundred on National Health notes the introduction into the United States Senate on Feb. 2 of an amendment by Mr. Owen to his bill for establishing a department of public health. This amendment aims to meet some of the objections that have been made to this measure by denying to the proposed department or its officers the right to enter dwellings or to intervene in the exclusive functions of the health service in the several states unless invited to do so, and by providing that in examinations for positions in such department "no discrimination whatever shall be made against any applicant on account of any system or school of medicine" to which he may have attached himself. Presumably this amendment will come up for discussion with the original measure at some future session of Congress.

## BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, March 14, 1911, there were reported to the Board of Health of Boston

the following cases of acute infectious diseases: Diphtheria 28, scarlatina 51, typhoid fever 5, measles 130, smallpox 0, tuberculosis 68.

The death-rate of the reported deaths for the week ending March 14, 1911, was 21.12.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, March 11, 1911, was 249, against 248 the corresponding week of last year, showing an increase of 1 death, and making the death-rate for the week, 18.85. Of this number 120 were males and 129 were females; 237 were white and 12 colored; 149 were born in the United States, 96 in foreign countries and 4 unknown; 50 were of American parentage, 173 of foreign parentage and 26 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 30 cases and 6 deaths; scarlatina, 46 cases and 6 deaths; typhoid fever, 4 cases and 0 deaths; measles, 108 cases and 0 deaths; tuberculosis, 76 cases and 19 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 38, whooping cough 3, heart disease 28, bronchitis 2. There were 7 deaths from violent causes. The number of children who died under one year was 48; the number under five years, 72. The number of persons who died over sixty years of age was 79. The deaths in public institutions were 107.

Diphtheria at Brattleboro. — On March 6 it was reported that five cases of diphtheria had occurred at the Memorial Hospital, Brattleboro, Vt., as a result of which the entire hospital was placed under quarantine. Three of the patients were nurses.

Seizure of Candy Eggs in Boston. — On March 9 the United States deputy marshal seized in Boston 131 boxes, containing a total of 26,200 candy Easter eggs, consigned to this city by firms in New York and Pennsylvania. The reason for this seizure was that the eggs are alleged to be coated with powdered talcum, which is held to be in violation of the pure food law and to render them unfit for human consumption.

A Living Centenarian. — Mrs. Robert Goddard, of Durham, Me., celebrated on March 10 the supposed one hundred and first anniversary of her birth by attending a meeting of the Society of Friends, at which she is said to have made an address lasting twenty minutes. She is reported to be in excellent health, though somewhat deaf. She has been twice married, but has been a widow for the past thirty years.

Protection of Food Exposed for Sale. — It is announced that, beginning on March 20, the Boston Board of Health will enforce strictly a regulation, made over a year ago, requiring that all dealers in this city exposing meat, fish, vegetables, berries and other articles of food must keep such stock under cover to protect it from flies, dust and other sources of contamination.

The Milk Problem in Massachusetts. — The recently published monthly bulletin of the State Board of Health of Massachusetts for January, 1911, contains a paper by Dr. Mark W. Richardson on "The State Board of Health and its Relation to the Milk Problem in Massachusetts," read before the Connecticut Valley Breeders' Association on Jan. 24.

Purification of City Water Supplies. — At a recent meeting of the Biological Society of the Massachusetts Institute of Technology, Mr. H. W. Clark, chief chemist of the Massachusetts State Board of Health, described various methods that have been employed for filtering the water supply of large cities and reported his investigation of some of the means of purifying water by electricity. In Europe, especially in France, experiments have been made with the ultra-violet rays for this purpose, but the ideal method of water purification on a large scale remains yet to be devised.

## NEW YORK.

Conviction for Opium and Cocaine Smuggling. — William Rind, first officer of the American Line steamship *St. Paul*, has been convicted of smuggling into the country cocaine and opium, as well as jewelry, and sentenced by Judge Hough, in the United States Circuit Court, to a year's imprisonment. When he was arrested bills showing the purchase of 213 two-ounce bottles of cocaine and considerable amounts of opium were found in his possession.

Proposed Restriction of Animal Experimentation. — A hearing on the bills to restrict animal experimentation before the Senate judiciary committee and the Assembly Committee on Public Health was held at Albany on March 8. Drs. Simon Flexner, James Ewing and William H. Park, of New York, and Dr. Walter B. Cannon, of Boston, spoke in opposition to the measures, and Dr. Herbert Snow was among those who appeared in advocacy of them.

Two Centenarians. — Mendel Diamond died recently at the home of the Daughters of Jacob, New York, at the reputed age of one hundred and nine years and ten months. As he was born in Russia, however, this extreme age would seem open to considerable question.

The Rev. Cicero Barber, said to be the oldest clergyman in the country, died at his home in Fort Edward, N. Y., on March 10, the supposed one hundred and first anniversary of his birth. He had been twice married.

Proposed Board of Inebriety. — Last year the legislature passed and Mayor Gaynor approved a bill authorizing the establishment by the city authorities of a board of inebriety for the compulsory control of habitual drunkards, but until the present nothing has been done towards carrying its provisions into effect. At the meeting of the Board of Estimate and Apportionment on March 9, the matter was taken up at the request of the State Charities Aid Association, which secured the passage of the bill, and a committee consisting of the presidents of the boroughs of Manhattan and Richmond was appointed to report in regard to it.

Diphtheria in Webster. — The village of Webster, in Monroe County, recently had occasion to report an epidemic of diphtheria, and called on the State Department of Health for assistance. While the initial cause was not absolutely determined, the investigation showed that the chief factor in the spread of the disease in the township apparently was the rural mail-carrier. Commenting on this circumstance, the health commissioner draws special attention to the fact that it is frequently the unrecognized mild case which disseminates diphtheria in communities. Cases of what are thought to be simple sore throat are not kept under observation, no cultures are taken, and the children are allowed to go among their associates as usual.

Passage of Cold Storage Bill. — On March 8 the Assembly, by a vote of 101 to 35, passed the Brennan Cold Storage Bill. It provides that all food kept in cold storage shall be conspicuously labeled with the date on which it was stored, that the label shall remain upon the goods at the time of their removal from the warehouse, and that once placed on the market for sale, they shall never be returned for cold storage. The time within which foods can be kept shall not exceed six months, except by special permission of the state commissioner of health, who is clothed with ample powers of inspection and supervision of the warehouses. Warehousemen must furnish quarterly reports stating in itemized particulars the quantity of each foodstuff kept in storage; they shall be granted permission to keep no product longer than a year, and transfers of food from one refrigerating warehouse to another in evasion of the law are prohibited.

Columbia University and the Presbyterian Hospital. — A meeting, on the invitation of Mr. and Mrs. Clarence Mackay, was held at the residence of the hosts on March 1 to discuss the affiliation of Columbia University and the Presbyterian Hospital. President Butler of the university presided, and addresses were made by Drs. Blake, MacCallum, Janeway and Schlapp, representing Columbia and the hospital, and Prof. Graham Lusk, of the University and Bellevue Medical College. The eventual placing of the Columbia Medical School in juxtaposition to the Presbyterian Hospital was foreshadowed in the remarks of Dr. MacCallum, who, after stating that he and his associates had good reason to rejoice over the improved opportunity for teaching and research afforded by the alliance of the two institutions, said the real opportunity — the new opportunity — in New York lay, he was convinced, in the building of the new hospital and the new medical school under practically one roof. Throughout the German universities such a condition existed, and this was the essential point, the fusion of the two in a group of buildings on one plot of ground. The chief source of good work was the concentration of the combined efforts of every one — teachers, students and hospital workers. Professor Lusk gave a note of warning, remarking that the greatest danger likely to threaten the scheme of union would be the sense of omniscience on the part of three human factors in the alliance, — the physicians, the hospital trustees and the authorities of the university. It was through a lack of willingness to make concessions that great schemes not infrequently failed of success.

Mortality Statistics for February. — The weekly reports of the Health Department show that during the month of February the mortality in the city represented an annual death-rate of 16.60, as against 16.54 in January and 16.93 in February, 1910. Among the diseases in which there was an augmented fatality were the following: The weekly average of deaths from typhoid fever increased from 5.5 in January to 6.25 in

February; the weekly average from measles, from 7.5 to 14.5; from scarlet fever, from 14 to 20.5; from diphtheria and croup, from 29.75 to 31; from epidemic cerebrospinal meningitis, from 6 to 7.25; from pulmonary tuberculosis, from 186.25 to 193.5; from acute bronchitis, from 22.25 to 23.25; from bronchopneumonia, from 107.5 to 117.75; from diarrheal diseases, from 39 to 49.25; from diarrheals in children under five years old, from 36 to 44; from appendicitis and perityphlitis, from 11 to 21.25. Among the diseases in which there was a diminished mortality were the following: The weekly average of deaths from influenza declined from 35.25 to 24.25; from pneumonia, from 172.75 to 158; from apoplexy and softening of the brain, from 35.75 to 28.5; from organic heart diseases, from 184.5 to 182.75; from cirrhosis of the liver, from 23.25 to 22.25; from Bright's disease and acute nephritis, from 123.25 to 118.75; and from puerperal diseases, including septicemia, from 15.75 to 14.75. For the first time in a very long period there were no deaths from malarial fevers. Usually one or two deaths from this cause are reported each month. The corrected death-rate, excluding non-residents and infants under one week old, was 15.69.

Attempt to Secure Patrick's Release. — The Medico-Legal Society, through a special committee appointed for the purpose, is to make application to Governor Dix for the setting at liberty of Albert T. Patrick, now serving a life sentence for the alleged murder of William M. Rice. This committee, composed of Clark Bell, LL.D., ex-president of the Medico-Legal Society; Prof. H. S. Eckels, of Philadelphia, and Dr. J. J. Kindred, member of Congress-elect from the Queens District of New York City, has also been authorized by the society to appeal to the bar, the medical profession and the public press for co-operation in securing his release. At a meeting held late in 1910 the society, by unanimous vote, gave as its opinion that Patrick was innocent of the crime of which he had been convicted, this opinion being based on the reports of two committees of disinterested and competent scientific men who had made exhaustive investigations of the case. Both committees conducted original experiments, and each declared that the death of Rice was due to natural causes; was not due to chloroform poisoning, as alleged, and that the evidence of the valet Jones at the trial was false, incredible and contrary to scientific knowledge; finding that death by chloroform could not have been produced in the manner described by Jones. The body of Rice was embalmed, and, as is well known, the conviction of Patrick was based on the presumption of the state that the embalming fluid did not and could not enter the lungs of the deceased. One of the committees, however, by embalming, under the supervision of Professor Eckels, of the School of Embalming, Philadelphia, the cadaver of a man of about Rice's age and build by the right brachial artery, in the same manner that the body of Rice was shown on the trial to have been embalmed, positively demonstrated that the embalming fluid did enter the lungs.

5. Bangs, L. B. *Bilateral Nephrolithiasis; Left Nephrolithotomy.*
6. Dawbarn, R. H. M. *Short Talks with My Students and Others; Being Random Suggestions for the Younger Practitioners.*

1. Abbe gives a history of the Dana operation — resection of the posterior spinal nerve roots — since its conception in 1888. The idea is to relieve pain by destroying the sensory tract (through ascending degeneration) into the spinal cord. The writer reports five cases operated upon by him — two of uncomplicated neuritis, two of spastic paralysis and one of sarcoma of the axilla. He suggests the possibility of using this operation in cases of tabes with severe crises and in spasmodic wry-neck. [L. D. C.]

3. Crile, in his excellent paper on Graves' disease, first analyzes the causes of the common post-operative hyperthyroidism and believes that we can reasonably exclude hemorrhage, infection, manipulating and cutting of the gland and, to a certain extent, the anesthetic *per se*, as causes of this condition. He believes, however, that the general anesthetic *per se* is a minor contributing factor and that local anesthesia *per se* is not such a factor. The psychic factor, therefore, remains as the principal cause of hyperthyroidism. To avoid this he has adopted the following technic: "The patient's reaction to small doses of morphine and scopolamine is ascertained. Daily inhalations, which are presumably for some medicinal purpose, but which are precise rehearsals of ether anesthesia, are practiced by the anesthetist. Ether is tentatively dropped on the inhaler along with the volatile oils, and the patient is cautiously, without her knowledge, tried out as to ether anesthesia — sometimes is completely anesthetized — all this in her own bed. The results are then studied and if the patient seems unsuited for the operation of excision, ligation is done as later described. If the central nervous system and the heart take the practice march well, the entire operation is then performed as follows: Long previous consent to an operation having been obtained, the patient is given morphine and scopolamine on the appointed morning, is kept absolutely quiet, is then gently anesthetized to the second stage, in bed as before, and is at once taken to the operating-room, where nitrous oxide is substituted for ether. The operative field is as completely cocainized as if no general anesthetic were being given. First the skin and fascia of the opposite side are incised about one inch. Through this incision, by means of a full-curved needle, the upper pole of the gland and all of the overlying tissue inclusive are firmly ligated. Then, in the gentlest possible manner, the opposite lobe is excised bloodlessly, absolutely avoiding traction on any uncocainized sensitive tissue precisely as if the patient were awake. After the operation, the utmost care is exercised to keep down to a minimum psychic and painful stimuli." For simple ligation the patient is made comfortable with morphine and scopolamine, told what is to be done, the skin fascia and muscles carefully cocainized and the poles ligated. Results with this technic have been extremely gratifying. The blocking of nerve impulses to the brain by cocainization is most important. The value of pole ligation, therefore, lies mainly in its breaking part of the nerve connection with the brain. It is possible that the cause of thyroid hypersecretion is a purely nervous reciprocal interaction between the thyroid and the brain. [E. H. R.]

THE ARCHIVES OF INTERNAL MEDICINE.

JANUARY, 1911.

1. *CHRISTIAN, H. A. *Observations on the Spirilla of Relapsing Fever.*
2. *PAGE, H. *Diphtheria Bacillus Carriers, with a Report of a Case Treated by Overriding the Infected Area with Staphylococcus Pyogenes Aureus.*
3. SWIFT, H. F., AND THRO, W. C. *A Study of Streptococci with the Complement-Fixation and Conglutination Reactions.*
4. *BYBEE, A., AND LORENZ, W. F. *A Report of Fifty Examinations of Cerebrospinal Fluid, with Special Reference to the Cell Count.*
5. OWEN, R. G. *Observations on Schuermann's Color Test for Syphilis.*
6. CRAIG, C. F. *Is Hemoglobinuric Fever a Manifestation of Malaria or a Disease Sui Generis?*
7. CROWDER, T. R. *A Study of the Ventilation of Sleeping Cars.*

1. Christian reports a case of relapsing fever in an immigrant. On the twelfth day of the disease the temperature rose abruptly and remained high for seventy-two hours, at the end of which fever terminated by a sharp crisis. During this period of pyrexia many spirilla were found in the blood and there was very rapid and very great enlargement of the spleen, causing intense pain. The spirilla were successfully inoculated into monkeys and white rats. In the monkeys the lesions found at autopsy were an accumulation of polynuclear leucocytes and endothelial cells in the sinusoids of the liver and a focal infiltration of the spleen with polynuclears.

2. Page, of Manila, writes an interesting paper on diphtheria carriers. He quotes the experience of Schiotz, of Copenhagen, who observed that a patient with staphylococcus sore throat placed in a diphtheria ward by error did not contract diphtheria; also that intercurrent attacks of staphylococcus sore throat cleaned up the Klebs-Loeffler bacilli in a few diphtheria convalescents. On the theory that the staphylococcus was the cause of immunity and also of cure, Schiotz inoculated six diphtheria carriers with staphylococci with complete success. The writer reports the case of a diphtheria carrier cured by overriding the infected area with staphylococcus pyogenes aureus. The patient's throat was sprayed with inoculated bouillon every two hours during the day. After two days a negative culture was obtained — the first since the disappearance of clinical symptoms eleven weeks before. Shortly before this treatment was instituted the patient complained of paresthesiæ and a test of her blood serum showed that she was manufacturing practically no antitoxin to neutralize the toxin constantly being elaborated in her throat. Page intended to give her weekly protective doses of antitoxin, but the elimination of the bacilli by the staphylococcus made this unnecessary. The writer concludes that pure culture of staphylococcus pyogenes aureus sprayed into the throat is capable of destroying the Klebs-Loeffler bacillus within seventy-two hours. The method is harmless and is indicated in all cases of diphtheria carriers. [See p. 169 of this volume of the JOURNAL.]

4. Bybee and Lorenz report on an elaborate study of the cerebrospinal fluid of fifty cases. They find the counting chamber the best method for examination of the cells. In their hands, all of forty clinically and cytologically positive cases of general paralysis of the insane gave a positive cell-chamber count, and in thirty-eight of these forty Noguchi's butyric acid test was positive. [L. D. C.]

3. Oliver discusses the pathology of electric shocks and burns as well as the cause of death in such conditions. He presents several illustrative cases with a brief note on treatment.

4. Crowe endeavors to throw light on the question as to whether the inoculation of tuberculin produces its effect in any degree by stimulating afferent nerve endings at the site of injection. He has carried on a series of experiments by injecting tuberculin along with a solution of cocaine. He concludes that if cocaine be thus used there is a distinct difference in the response to the inoculation of tuberculin, the proof of this resting on the form of opsonic curve following such doses as compared with doses with which no tuberculin was given. He believes that there is a possibility that tuberculin does produce part of its effect by stimulating the central nervous system, and that such stimulation may take place at the site of inoculation.

5. Leipoldt reports his results with the use of "pantopon" in place of scopolamine-morphine as a preliminary to general anesthesia. "Pantopon" is a combination of twenty of the alkaloids of opium. [J. B. H.]

2. Holmgren has found that if an acid fluid is dropped on an absorbing surface such as filter paper the water extends further from the central point than the acid. Thus by use of Congo red paper he has worked out a method of determining the amount of free acid in gastric contents by the radius of the acid reacting circle. His results from this method have been very uniform. The value of the test is that only a drop of stomach contents is necessary.

3. Forlanini has followed two cases that have recovered from artificial pneumothorax as a cure for tuberculosis. Although these cases are too few upon which to base any definite conclusions, he found that the lung did not return to its former capacity. Also, he found that the length of time of the pneumothorax affected the ability of the lung to expand again. The amount of scar from the tubercular process also plays an important rôle. Therefore, he advises further study of the question and considers that the most favorable cases for this treatment in regard to the end results on the lung are cases with small processes in which the pneumothorax will only have to be kept up a short time. [C. F., Jr.]

8. Wenckebach, K. F. *A Decisive Frequency of the Heart in Parozysmal Tachycardia.*
9. Aschoff, L. *Remarks on the Work of Schlæpfer.*

1. In a long article, Grafe reports his investigations on the results of the study of metabolism in acute infectious diseases. He considers that in addition to the increased heat production there is also an injury to the mechanism controlling the heat-regulating centers. He considers that the carbohydrates play by far the most important part in preserving the weight of patients with acute febrile disease, as by far the most heat is formed by their combustion, and if there is not an excess of this food the nitrogenous elements of the body are burnt and weight and strength lost.

2. Skoonjakoff has shown by experiments on rabbits that in anemia following hemorrhage blood formation occurs in the spleen and slightly in the liver. The same condition has been shown in toxic anemias by other authors. This extramedullary blood formation only comes on after a few weeks to a few months.

4. Jerusalem found upon histological examination of the stomach in cases that died during the course of acute infectious fevers certain changes in all cases except in whooping cough. The lesion usually consisted of invasion of the interglandular tissue with cells of the lymphocytic series and fibroblasts. He does not consider that it is safe to conclude that these lesions are the cause of the gastric symptoms occurring in acute infections. Also, it seems strange that the lesions should be the same in the different diseases.

5. Oppenheimer gives the technic of the tryptophane test for gastric cancer and also a new test with 3% acetic acid. Both of these tests are not infallible, but he considers that they are of considerable value in making an early diagnosis. [C. F., Jr.]

1. From extensive experimental and histologic studies in vascular surgery, Curcio concludes that arterial and venous suture should always succeed, that transplantation of veins into arteries is the ideal treatment of aneurysm, and that arteriovenous anastomosis is a useful procedure if practiced early. [R. M. G.]

## Miscellany.

### REPORT OF THE COMMITTEE OF THE AMERICAN NEUROLOGICAL ASSOCIATION APPOINTED TO INQUIRE INTO THE OCCURRENCE OF MENTAL DISEASE AMONG PERSONS EMPLOYED BY TRANSPORTATION COMPANIES, MADE TO THE ASSOCIATION AT THE MEETING IN WASHINGTON, MAY, 1910.

The committee appointed to inquire into the occurrence of mental disease among persons employed by transportation companies at the meeting of the American Neurological Association at Washington in 1907 make the following report:

We have made special inquiry as to the occurrence of general paralysis of the insane among such employees, because the statistics are more readily accessible, because it most frequently attacks men in the full vigor of their activity, because its onset is insidious and it invariably leads to profound mental deterioration, with marked loss of memory and failure of judgment and decision. If there be a considerable amount of general paralysis among such employees, it is obvious that this alone is a source of danger, from which the public should be protected. An investigation into the occurrence of other diseases, such as the other forms of insanity, epilepsy, arteriosclerosis, etc., would demand much longer investigation, and would add merely cumulative evidence.

We wish here to express our thanks to the various superintendents of hospitals for the insane in New England, New York and Illinois; to Dr. Gregory, of the psychopathic ward at Bellevue Hospital, New York, and to Dr. Dewey, of the Institutions Registration Department in Boston, for their co-operation and efforts, without which our researches would be far less complete.[1]

An attempt was made to discover whether any accidents had occurred as a result of the mental disease, but in very many cases it was impossible to get information. Several of the superintendents kindly wrote making inquiry about every case, but most of the letters were returned unopened and they received very few replies.

As a result of these investigations, therefore, the committee has come to the following conclusions:

A considerable number of cases of general paresis and other forms of mental disease are to be found among railway employees.

I. Out of 5,832 commitments, 60 were of railway employees (over 1%).

II. Out of 1,905 male paretics seen in city clinics, 40 were railway employees (nearly 4%).

III. Out of 2,083 paretics at present in hospitals for the insane, 102 were railway employees (nearly 5%).

IV. The examining physician for two railway companies has noted in four years, among the employees of these companies, 26 cases of mental disease, 15 of which were cases of paresis.

We have been unable to discover any fatal accidents due to the mental incompetence of such employees, but we have learned of several accidents, unattended with loss of life, due to this cause, and several cases in which accidents have been narrowly averted. It is obvious that it is a source of danger to the community to keep persons suffering from paresis and other mental diseases in responsible positions in the railway or marine service. Such danger can be averted or at least diminished by the examination, at repeated and regular intervals, of all employees holding responsible positions.

Philip Coombs Knapp,
Charles L. Dana,
Hugh T. Patrick,
Frank R. Fry,
*Committee.*

[1] The original report gives detailed statistics in tabular form.

### EDUCATION IN "SEX HYGIENE."

The problem of so-called "sex education" for children is one which, in common with those of eugenics and venereal disease, has been receiving considerable attention of late, particularly before various women's clubs and charitable organizations. Doubtless it is desirable that so important a question should be thoroughly discussed, and it is certainly well that not only the advantages but also the possible risks of such indiscriminate education should be considered. In this connection, some very sane comments were made by Dr. Richard C. Cabot in an address on March 4 before the 1915 Conference of Women's Clubs in Boston. A part of Dr. Cabot's address as reported in the daily press was as follows:

"In connection with the tremendous problem of sex hygiene, we are in danger of seizing upon a panacea that will do us more harm than good — the teaching of sex hygiene in the schools. Although doctors and parents should know about these matters, they shouldn't spin that knowl-

edge out to children. The temptation to do this as a preventive measure is great, but the process is not wise. I don't believe in teaching maternity through natural history, and sex hygiene through biology. It is the influence of pure personalities whom we meet that keeps us straight, not fear nor knowledge. Hygiene has no word to say why people should behave themselves. It is obviously the field of the educator and moralist. We often believe that disease is the result of sin. There's nothing in it.

"Whether people who misbehave shall contract disease depends on the money, cleverness or luck of the individual. The sin isn't different, whether you suffer for it or not. There is no good science behind the idea that hygiene can guide us in this matter. It is bad morals to reason so.

"If you lie, you may get insomnia thinking about it, and insomnia hurts the health. Don't steal or you may get into jail, and jails are unsanitary and so injurious to the constitution. These things are no sillier than to say 'behave yourself or you may suffer for your misdemeanors.'

"We must not go too hastily about this business. It requires careful deliberation. The problem is as old as humanity. There's no reason to think we are worse off than humanity has ever been before. Indeed, there is some reason for thinking we are better off."

Dr. Cabot's remarks and opinions seem particularly pertinent and worthy of consideration. Because a thing is true, it does not necessarily follow that it should be immediately taught to every one, and in the teaching of sex hygiene in the schools there is opportunity for injudicious enthusiasts to do harm. Neither hygiene nor biology can be expected wholly to solve the problems of ethics. Knowledge of facts, though valuable in itself, is not always enough to determine right conduct; and in the sex education of children, it should be remembered that there are times when the letter, even of truth, killeth.

## PHYSICIANS AS PRISON WARDENS.

A COMMUNICATION from Dr. Beverley Robinson, of New York, calls attention to the great responsibilities of wardens in penal institutions and the consequent importance of securing for these positions persons with the requisite qualifications of knowledge, tact, judgment, forbearance and kindliness. Dr. Robinson believes that physicians are most likely to possess these qualities, and, therefore, advocates their appointment to such positions, which should be made attractive to men of experience and of the most desirable type by increased salary and long tenure of office. In such an executive situation, a physician could probably do more for the health and well-being of prisoners than could a lay warden or than he himself could in a purely professional subordinate position. The feasibility of securing suitable physicians for these posts might be an open question.

# Correspondence.

## A LETTER FROM BERMUDA.

HOTEL HAMILTON, BERMUDA,
March 6, 1911.

*Mr. Editor:* As little, if anything, pertaining to these Islands has appeared in the JOURNAL of late years, it may be of interest to some of your readers to have their attention called to the advantages and disadvantages of this place as a winter resort for people from "the States."

That the islands are popular is evident from the fact that between nine and ten thousand visitors come here annually, and many return year after year. Seven hundred miles from New York, or less than forty-eight hours' sail, brings one to this land that never knows frost nor snow and ice, but has perpetual vegetation.

Leaving New England early in February, as did the writer, in a howling blizzard, the contrast was striking as well as deceptive. Here the sun was shining brightly, the air was rather sultry, the birds were singing, the flowers were in bloom, the strawberries were ripe, many people were dressed in white and it seemed as if we had suddenly entered a land of perpetual summer.

The deception, however, was of short duration, as within twenty-four hours the wind had changed from the south to the northwest and many of the recent arrivals were shivering with cold. Our usual winter clothing was in demand and has been worn ever since. It is a mistake to change one's clothing for lighter weight until compelled to do so. Many visitors from the North fail to realize the altered conditions under which they are placed here, and hence do not take proper precautions against taking cold. Colds are very prevalent here among the newcomers, and the cause is not far to seek. Accustomed as the Americans are to warm houses at any and all times of the year, they come here in the cold season to hotels and boarding houses that have little or no means of heating the rooms. Too often they are also induced by the marked change in the weather from that left behind them a few days previously to put on lighter clothing, as they see others have done. The result is that in a short time many of them are the victims of a good old-fashioned New England cold, or possibly of something worse, as a "bowel complaint," etc. About this time they begin to growl about the so-called "warm climate" and wish themselves in a place where they could turn on the heat and be comfortable. Such has been the writer's experience in Southern California, in Florida, in Italy, in Egypt and in Bermuda.

The English people suffer less in this respect than the Americans from the fact that they have always lived in houses in which the temperature is seldom over 60° F., while in our houses it is usually about 70°. Ignoring the question as to the wisdom of the Americans keeping their houses too warm, the facts are as above stated, and they are to be reckoned with in traveling in the warmer climates.

The winter temperature of Bermuda is about 60°, varying from 50° to 70°. That would seem warm and comfortable to a New Englander, but one's comfort does not depend solely upon temperature. Dampness and rains are important factors — and they are very commonly in evidence here. Warm in the sun, cool in the shade, is the rule here, as it is in most warm climates, and visitors from the colder regions must be guided and guarded accordingly in the way of clothing and warm rooms.

The visitor's experience justified him in asserting in the most positive terms that all hotels and boarding houses, wherever located, which care for the patronage of the American public should have facilities of some sort for heating the sleeping and living rooms at any and all times. Young people who spend most of their time in the open air and lead an active life may not require warm rooms, but the middle-aged and elderly people frequently wish to retire to the quiet and seclusion of their own apartments and they naturally want them to be safe and comfortable, as they are accustomed to have them at home. They are

able and willing to pay for these comforts and will be satisfied with nothing less.

The Flagler hotels on the east coast of Florida, and the Plant system on the west, realizing the importance of this need, have provided facilities for heating their houses, to the very great satisfaction and comfort of their patrons. Some of the first-class hotels in Southern California have also swung into line by providing heat for their guests. The sooner the hotels in Bermuda furnish like facilities, the better will it be in all respects for every one interested. Sick folks, as a rule, are better off at home than anywhere else. Neither climate nor change in locality will compensate for the comforts of home. Those people who are only half sick and can put up with things as they find them, and need to get away from business or other tiresome conditions, are often benefited by a trip. Convalescents and those who are the victims of "brain fag" or nervous exhaustion might find Bermuda very agreeable for a few weeks, or perhaps months, between November and June. With proper precautions they would be enabled to spend a large part of their time in the open air. If unable to do that, then Bermuda is no place for them.

Tourists and tuberculosis are financially incompatible. The former are welcome here; the latter is not. The universal testimony that the victims of this infection do badly here is probably correct by reason of the dampness and cold, the former being in evidence at all times and the latter during the winter months. At all events, Bermuda is no place for that class of invalids under present conditions.

Rheumatism is found here, as it is in every place known to the writer. Dampness, especially when accompanied by cold, is not conducive to the comfort of rheumatics. A warm, dry climate would seem to be the most favorable one for these people. Yet other factors than climate have much to do with the production of this widespread and troublesome affection. For a long time the writer has entertained the idea that the diet is often the chief factor in causing rheumatism, and that if we ever conquer the disease, it will be largely accomplished along these lines. Many people keep themselves fairly free from rheumatism by carefully regulating their diet for long periods of time, whereas otherwise they would be more or less disabled by the infection.

Typhoid fever prevails here to a certain extent, and any one having experienced the affectionate habits of the Bermuda flies can readily believe that they have something to do with the transmission of the disease. Sanitation is at a rather low ebb. Many of the inhabitants are poor and ignorant and do not trouble themselves about these things. Their salvation seems to rest largely upon their outdoor life.

The water supply of the Islands is peculiar from the fact that there are no springs or brooks of fresh water here. The Islands are formed largely of sandstone and limestone, which is so porous that it is impossible to sink wells below high tidewater level without their containing salt water. A few, however, are still in use, as in times of drought fresh water becomes very scarce and the rain water, which percolates through the thin layer of soil and the sandstone, does not readily mix with the sea water, thus answering very well for laundry and various other purposes. In time, however, this well water becomes brackish and is laxative in its effects upon man and beast.

The only fresh water here is rain water. It is obtained from the roofs and from artificial watersheds. The former are made of slabs of limestone, frequently whitewashed, and connected with tanks proportionate in size to the probable needs of the occupants of the premises.

The watershed is made by removing the thin layer of soil from the side of a hill, covering the underlying rock with cement, whitewashed frequently, and connecting it with a reservoir of the requisite capacity. Every house is required by law to have a roof suitable for shedding the rain water, and a tank for the storage of the same.

Properly cared for, this arrangement gives pure water; and, of course, is free from any contamination by sewage, etc. Prolonged droughts give rise to much inconvenience and even suffering from the scarcity of pure water, to say nothing of the harm to the crops that depend so much upon a sufficient supply of water.

From the fact that "rain fell on two hundred and twelve days in 1909, and the official total measurement was 69.16 inches," it would seem possible with proper facilities to secure fresh water in sufficient quantities to last through any drought that is likely to occur. When the Boer prisoners were confined here, the government established plants for condensing sea water similar to those in use upon ocean steamers, but they are not used generally at present, the tank supply being sufficient for all ordinary seasons.

The scarcity of water precludes any system of drainage as a general rule, and house sanitation depends largely upon cesspools and dry closets.

The population of the Islands is about 19,000. Two thirds of the inhabitants are colored. While vital statistics are not as reliable as could be wished, yet the death-rate is stated to be 22 to the 1,000. Forty-two per cent of the mortality occurs in early childhood, largely among the colored people.

The method of disposing of the dead is peculiar, depending, of course, upon the conditions present. The soil here varies in depth from a few inches to a few feet, generally not over two or three. For this reason vaults, or chambers, 10 or 12 feet deep, are cut in the soft sandstone of sufficient length and width to receive the caskets.

The well-to-do people own and control their lots, but many are unable to do this, by reason of the expense. By paying a small sum ($5.00) a body can be placed in a vault, which is sealed up and not allowed to be opened again for one year. Every year, however, a body can be put into that vault, so long as there is sufficient space. As the coffins are simple and made of the cheapest wood, and as the rock is very porous, the vaults are many years in being filled, even if they are ever full. They are never cleaned out, as is done in some of the vaults in some foreign cemeteries. The wells here are so few and so far removed from the cemeteries that there can be little danger of infection by the seepage of rain water.

While it may be a far cry from the cemetery to the police court, yet this rambling letter may well close with a brief account of a trial witnessed by the writer, which affords a good example of English thoroughness and commendable justice.

On account of jealousy, for which there was doubtless ample reason, a white woman attacked a colored one on the street, and, getting the worst of the scrimmage in the way of bites and scratches, she enters a suit against the colored woman for assault and battery. After hearing the testimony of the parties and their witnesses, the magistrate, realizing the partisan character of the same, of his own motion sent a constable to bring a carpenter into court as an impartial witness.

This man from the humbler walks of life had seen the fight, but knew neither party and told a simple, straightforward story, which impressed his disinterested hearers as being the truth.

From his complete and careful notes the magistrate reviewed the case in a most thorough manner, expressing his opinion of the evidence as given by different persons, and concluded by discharging the prisoners, giving his reasons clearly and distinctly for his action. The trial occupied several hours and was conducted in a most admirable manner throughout.

Imagine a magistrate in Massachusetts, of his own motion calling in an outside witness to clear up a mass of conflicting evidence; yet who can doubt for a moment the great value of such action as shown in the case above outlined. It would seem to a layman as if the American system of trials might well take a leaf from the English methods, thereby insuring more thorough procedures and more exact justice.

Bermuda is an interesting place to visit. Aside from its historical interest, there is much to see in the way of scenery; plants, flowers and vegetation strange to a northerner; the barracks and dockyards; the caves, the sea gardens, the aquarium, the "devil's hole," the peculiar rock formation and the action of the ocean thereon, etc. One of the islands, St. Georges, was headquarters for many of the blockade runners during the Civil War. Business was booming there for a time, but went to pieces, of course, with the Confederacy, leaving many of the people poorer than they were "before the war."

The chain of principal islands is about twenty-five miles

in extent, furnishing a hundred miles or more of pleasant rides, over fine roads for the most part, and in all directions. There are no street cars nor cars of any sort. Carriages are reasonable and taking care of visitors is the chief occupation of a large proportion of the people. The chief precaution for the newcomers to take is to keep warm, especially while riding, and not to be deceived by the sunshine, the perpetual foliage and the reflection that, as they are in a "warm climate," they need pay no attention to personal comfort as regards heat and cold.

Very truly yours,

GEORGE W. GAY, M.D.

## RELATIVE TO CLIMATE IN HAY FEVER.

BOSTON, March 10, 1911.

*Mr. Editor:* The writer, last summer, spent his vacation in California and the Canadian Rockies; for ten years he has been more or less bothered with hay fever, and at no place of the many where he has been, including mountains and sea resorts, has he ever found complete relief, although he has had his nose well operated upon and keeps himself in excellent health, until the past summer, when he spent most of the hay-fever season in Santa Barbara, Cal. Here he did not have a particle of trouble in any way; this is especially interesting, because there is no altitude at Santa Barbara, excepting back on the hills, and the air is very humid.

In the Canadian Rockies, at Laggan, at the most picturesque spot in America, Lake Louise, which is 5,600 feet above the sea-level, and where snowcapped mountains and glaciers are all around you, he found almost complete relief, but not the absolute ease and comfort that he did at Santa Barbara.

Dr. William H. Flint, who lives there, says that in his experience Santa Barbara is outside of the hay-fever belt; it would probably be more accurate to say that he does not see hay fever in Santa Barbara.

Very truly yours,

F. W. HORNBROOK, M.D.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, FEB. 25, 1911.

## APPOINTMENT.

PROF. THEOBALD SMITH has been appointed a member of the National Referee Board of Consulting Scientific Experts (of which Dr. Ira Remsen, president of Johns Hopkins University, is chairman), to fill the vacancy caused by the death of Prof. Christian A. Herter, of New York.

## SOCIETY NOTICES.

THE HARVEY SOCIETY.—On Saturday evening, April 1, at 8.30 o'clock, Dr. S. Weir Mitchell, of Philadelphia, will deliver the last lecture of the season at the New York Academy of Medicine. The title is: "A Lecture on William Harvey, the Discoverer of the Circulation of the Blood."

MIDDLETON GOLDSMITH LECTURE.—The Middleton Goldsmith Lecture of the New York Pathological Society will be delivered at the New York Academy of Medicine on Saturday evening, March 18, at 8.30 P.M., by Prof. Frank P. Underhill, of Yale University. Subject: "A Consideration of Some Chemical Transformations of Proteins and Their Possible Bearing on Problems in Pathology."

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A meeting of the society will be held in John Ware Hall, Medical Library Building, on Monday, March 20, 1911, at 8.15 P.M. Addresses: "The History of the Royal College of Physicians of London," Dr. Thomas McCrae. "Some Medical Gossip Pertaining to the Last Illness of Queen Anne of England," Dr. Charles G. Cumston. "Science at the Medieval Universities," Dr. James J. Walsh. Members of the Suffolk District Medical Society are cordially invited to attend.

ROBERT M. GREEN, M.D., *Secretary*,
78 Marlborough St.

NEW ENGLAND PEDIATRIC SOCIETY.—The fifteenth meeting will be held in Sprague Hall, Boston Medical Library, 8 The Fenway, on Saturday, March 25, 1911, at 8.15 P.M. The following papers will be read: (1) "A Case of Oxycephalus," Arthur Willard Fairbanks, M.D., Boston. (2) "Report and Consideration of Two Cases of Scurvy," Fred P. Webster, M.D., Portland, Me. (3) "The Value of Direct Inspection of the Larynx, Trachea and Bronchi in Children," D. Crosby Greene, Jr., M.D., Boston. (4) "A Directory for Wet Nurses; Its Experiences for One Year." Fritz B. Talbot, M.D., Boston. Light refreshments will be served after the meeting.

JOHN LOVETT MORSE, M.D., *President*. FRITZ B. TALBOT, M.D., *Secretary*.

MASSACHUSETTS GENERAL HOSPITAL, SKIN DEPARTMENT. MEETING CONCERNING THE USE OF SALVARSAN.—On Tuesday, March 28, 1911, at 11 o'clock in the morning, there will be held in the lower amphitheater of the Out-Patient Department of the Massachusetts General Hospital a special meeting, under the auspices of the Skin Department, concerning the new Ehrlich-Hata arsenical compound "Salvarsan." Dr. W. F. Boos will speak on the chemistry of the drug, Mr. Joseph Godsoe will demonstrate its actual preparation for injection, Dr. R. P. Towle will describe its clinical results and its applicability. Dr. F. S. Burns will demonstrate its intramuscular injection, and Dr. Hugh Cabot, the intravenous method. You are cordially invited to attend this meeting.

FREDERIC A. WASHBURN, M.D.,
*Resident Physician*.

## RECENT DEATHS.

HENRY PICKERING BOWDITCH, M.D., M.M.S.S., died in Jamaica Plain, March 13, 1911, aged seventy years.

DR. WILLIAM WHEELER HEWLETT, a prominent physician of Babylon, Long Island, N. Y., and former president of the Suffolk County Medical Society, died suddenly on March 5, at the age of sixty-three years. He was graduated from Bellevue Hospital Medical College in 1869.

DR. JOHN W. COE, JR., of New York, died from pneumonia, at the Presbyterian Hospital in that city, on March 6, in his thirty-ninth year. He was graduated from Johns Hopkins University in 1898, and at the time of his death was dermatologist to the Presbyterian Hospital.

DR. HOSIAS M. SCHIEMANN of New York, died at the Mount Sinai Hospital on March 10, in consequence of an elevator accident in January, which rendered necessary the amputation of his leg above the knee. He was a native of Russia, where he was graduated at Kasan in 1869, was forty-eight years of age, and had practiced in New York about four years. Previously he had for some years held a government position in Russia, but was obliged to leave that country on account of the persecution of the Jews.

## BOOKS AND PAMPHLETS RECEIVED.

Collected Papers. By the Staff of St. Mary's Hospital, Mayo Clinic, Rochester, Minn., 1908-1909. W. B. Saunders Co. 1911.

Diseases of Children for Nurses. By Robert S. McCombs, M.D. Second edition. W. B. Saunders Co. 1911.

JOHNS HOPKINS HOSPITAL LIBRARY

## Public Lecture.

# POPULAR FALLACIES ABOUT INSANITY.*

BY HENRY R. STEDMAN, M.D., BROOKLINE, MASS.

If we look at insanity from every point of view we must admit that there is no disease which is more dreadful and at the same time more far-reaching in its relations and its consequences. As if this were not enough in itself, it has been invested in the public mind with many needless terrors and misconceptions because of the extreme popular ignorance that prevails regarding its true nature and extent. Some of these I shall try to dispel.

### THE ALLEGED INCREASE OF INSANITY.

The familiar question, "Is not insanity increasing very fast?" which is raised by people in general and many physicians who have not informed themselves of the true situation, shows the general belief regarding the prevalence of the disease and, if we consider only the great accumulation of the insane in our hospitals, it is a natural one. According to the last complete United States census report (1905), the total number of the insane in institutions in this country on Dec. 31, 1903, was 151,151, and the number of hospitals, 328, while in 1890 the number of insane was 74,028 in 162 hospitals, an increase of more than 100% in the number of hospitals for the insane. Then also, in England, one individual in every 278 of the general population is insane, and very similar figures are reached in the more densely populated states of this country. Moreover, the mass of the mentally defective, from the nature of their disease, cannot be treated at home like most patients with physical maladies, but require care in large institutions, which are sadly in evidence in every section of the more populous states of the country. These conditions make great impression on the public mind and have led to the widespread belief that there is a great and rapid increase of this particular disease which far outstrips the growth of the general population. It is, nevertheless, a great mistake to draw the conclusion that the increase in the insane population of our hospitals necessarily indicates that the disease insanity is itself increasing. These accumulations are, in point of fact, only in small part due to an increase in the number of newly occurring cases which is the only true measure of the prevalence of a disease.

You will ask, "What, then, are the causes of these appalling aggregations of insane persons?" Many factors contribute:

1. Patients do not die of insanity itself, — except suicides and a very small number of cases which succumb to the exhaustion of acute delirious conditions, — and but a comparatively small proportion recover, the tendency of the disease being to become chronic — the mind deteriorating while the bodily condition holds good. Therefore, it happens that a far smaller number are discharged each year from our hospitals or die there than are admitted, and the result is a steady accumulation of chronic cases. This is plainly shown by the recent finding of the Massachusetts Board of Insanity that since 1880 the annual accumulation-rate of the insane in that state had increased five times as fast as the admission-rate of new cases.

2. At least three fourths of all admissions to our institutions for the insane are (*a*) chronic and incurable cases drawn from the reserve of insane patients in the community; (*b*) old hospital patients who, formerly discharged as improved, have been obliged to return through inability to adjust themselves to outside life; and (*c*) relapsed cases whose insanity has taken the form of repeated attacks from which they only temporarily recover.

3. More mental conditions are now called insanity than formerly and are so pronounced by physicians. We must, therefore, know just what insanity is before we can ascertain with some approach to accuracy the actual prevalence of the disease. This cannot be accomplished until we have a uniform and expert system of classifying the form of mental unsoundness in each case. Take senility, for example. The enfeebling of the mind and body in the aged which not a great many years ago would have been generally looked upon as a natural result of old age, an evidence of dotage and a condition which could and should be cared for at home, is now often regarded as a symptom of insanity sufficient to justify commitment to a hospital. Moreover, such cases are now thought to be the better for such special care; 19.71% of new admissions to the Massachusetts hospitals for the insane to-day are of persons over sixty years of age, which is double the percentage in 1880. Thus the admission of the aged, also, to hospitals for the insane has greatly increased their population without augmenting the amount of freshly occurring insanity.

4. The growing practice of placing the dependent insane under State care has led to the transfer of many patients to State hospitals from almshouses, who, though long insane, had not been up to that time so registered. Far from being new cases of insanity which contribute to the increase of the disease, they are patients of very long standing, now for the first time rightly labelled, who simply go to swell the number of chronic patients.

5. Under the more advanced modern methods the medical treatment given the insane in hospitals is of better quality, with the result that while they live longer and their mortality-rate is diminished, they accumulate faster.

6. The better management of public hospitals as well as the care afforded the inmates, the increased safeguards against improper commitment, etc., have greatly lessened popular prejudice and distrust and led people to entrust their relatives to public care much more willingly and freely.

7. The great growth of "flat-life" in the last

* Delivered in the Free Public Lecture Course on Medical Subjects at the Harvard Medical School, Feb. 2, 1908 (revised).

ten or fifteen years has, it is thought, had no small share in increasing the number of public insane. People living in such close quarters have neither the accommodation nor the privacy for retaining in their homes members of their families who are mentally afflicted.[1]

8. Wise legislation has, as the director of our last national census believes, accelerated the influx to the hospitals in many places by taking the incurable, criminal and epileptic insane and feeble-minded from the others and placing them in special institutions.

9. There have also been more complete returns of the existing insane to swell the reported number. Their enumeration becomes much more comprehensive with each succeeding census.

These facts show plainly that the increase in the number of insane patients cared for in institutions is by no means an index of the increase of insanity in the community, but far more nearly a measure of the frequency with which people nowadays resort to hospitals for the insane. In this connection the criticism of Lugaro, a master-mind on all questions relating to mental disease or defect, is very much to the point. In writing on the prevention of insanity in his work on "Modern Problems in Psychiatry," he cites facts to show "how unfounded is the pessimistic prejudice of those who, mistaking an increase of the numbers of persons under asylum treatment for a real increase in insanity, make statements calculated to alarm the public and accuse civilization of exacting from the human brain an excessive amount of activity."

But in order to obtain direct and positive data by which to ascertain whether this or any other disease is increasing, it is essential to know the proportion of *freshly occurring cases or first attacks* to the population at different periods. This is especially true of insanity and is now generally recognized by competent investigators familiar with the disease as the crucial test. Its neglect has vitiated much statistical work and has impaired the value of our national census.

This enumeration is made by calculating the annual number of *first admissions* to institutions for the insane, that is, the number of persons who have never before been in a hospital of the kind, and then comparing this with the number by which the general population has increased in the same year. By repeating this calculation each succeeding year we ought to be able to arrive at a fair estimate of the prevalence of the disease. Unfortunately first admissions do not always mean first attacks of the disease and the accounts given of previous residence in hospitals and the disease-history of most public patients (especially the foreign-born) are apt to be most unreliable. Another discrepancy appears in the fact that over 40% of these supposed new cases admitted for the first time have been insane for more than a year and are already chronic cases. First admissions, therefore, can only approximately represent the occurring insanity of a given year. In spite of these drawbacks, however, first admissions are the only true guide to follow, and when, as we hope, they are given in the future, the close analysis they require as a part of an improved system of statistics, will without doubt throw much light on this important social and statistical problem.

Information on this important point as it affects this country is very meager. The last United States census report (1905) contains many statistical tables and other interesting information relating to the insane of the country, but in an elaborate inquiry into the increase of insanity omits all reference to this vital factor of first admissions. Tables of first admissions are, it is true, published in the hospital reports of some of the States, but they are utterly inadequate as a basis for estimating the increase of occurring insanity in the whole country, and the annual proportion of these new cases to the general population nowhere has been computed so far as we can ascertain except in recent reports of the Massachusetts State Board of Insanity.

Dr. Copp, the executive officer of that board, in a recent paper on the subject, gives a chart covering a period of twenty-nine years ending in 1909, which shows the very wide divergence between the curves representing the accumulation of the insane and that for the admission of the newly occurring cases in the hospitals of that State. As a result of his investigations, he concludes that the rate of increase of insanity in proportion to the population is only "slight" and "not at all alarming." Unfortunately his statistics relate to a comparatively small section of the country and one in which the rate of immigration is nearly equal to the increase of population; where, also, from 42.14 to 46.26% of first admissions to the state hospitals are foreign born, "justifying the conclusion that foreign immigration tends to increase occurring insanity."

We must, therefore, turn to Great Britain, where the proportion of the insane to the population corresponds closely to ours, where the population is far more stable and where the question of the increase of insanity has been carefully studied for many years by competent investigators.

Fifteen years ago, D. Hack Tuke, the famous English alienist, after an exhaustive analysis of the various arguments and statistics bearing on the subject, particularly those relating to first admissions, announced that "statistical returns in England and Wales do not support the opinion that a distinctly larger number of persons in proportion to the population become insane than was formerly the case.[2]

The last annual report of the Board of Commissioners in Lunacy for Scotland which has 18,337 insane inhabitants, gives a table showing the proportion of pauper lunatics never previously registered per 100,000 of the population for each year from 1900, — when it was 50, — to 1909 inclusive, — when it was 43. "It will be seen," the report states, "that these figures show a persistent and substantial decrease throughout

[1] Jour. Roy. Statist. Soc., June, 1907, p. 234.

[2] Dict. Psychol. Medicine, p. 1196.

the last quinquenniad, and an examination of the figures on which they are founded shows, as in the case of the other tables, that the decrease is confined to no special county or district, but is spread over all parts of the country." The commissioners comment on the situation as follows: "In our forty-sixth annual report we had occasion to record for the first for nineteen years a fall in 1903 in the number of pauper patients in establishments in proportion to population. The results of the retrospect now (1910) submitted are such as to show that there is reason to believe that the year 1903 marked a true turning-point and that no permanent increase in the amount of registered insanity is likely to occur in future under present conditions beyond the almost inevitable rise due to increase of population, or such as may result from mere accumulation through a diminished rate of discharge."

In England and Wales the insane number 130,553. The statistical tables in the report of the Commissioners on Lunacy of those countries for 1910 show that the proportion of first admissions per 10,000 of the population has fallen from 5.76 in 1902 to 4.99 in 1910. These are very significant facts, but — as is pointed out — "this diminution in the rate of increase, although it has persisted for several years and corresponds to a similar diminution in Scotland and to some extent in Ireland, cannot be accepted as yet as positive evidence of an actual *decrease*. The social and economic causes leading to fluctuations extending over several years are too complex to be briefly stated, but the present variation probably gives more reason for hope that the high-water mark of insanity has been reached than any fluctuations of previous periods."

Finally, Humphrey, an English investigator and medallist of the Royal Statistical Society of London, a most competent expert and an eminent statistician, after a second elaborate and exhaustive study of the question after a lapse of seventeen years, feels justified in expressing "a decided opinion that there is no absolute proof of actual increase of occurring insanity in England and Wales," and his inquiry "further strengthens the conviction, expressed in the former paper, that the continued increase in the number and proportion of the registered and certified insane reported on from time to time by the Lunacy Commissioners is mainly, if not entirely, due (*a*) to changes in the degree and nature of mental unsoundness for which asylum treatment is considered necessary or desirable; and (*b*) to the marked decline in the rate of discharge (including deaths) from asylums; in fact, that this increase of the registered and certified insane" is due to causes of the same general nature as those that I have enumerated, and is "not really the result of increased prevalence of insanity as a physical disease." [3]

In short, extensive research by the most competent investigators with the aid of all the statistics and other sources of information that are available has thus far failed to reveal any appreciable increase of insanity that cannot be accounted for by increase of the population. It is, of course, possible that more precise data and more systematic and uniform classification based upon expert knowledge might modify this conclusion, but under present conditions there is certainly nothing to warrant the popular and in some quarters the professional alarm that is now felt over the terrible and incalculable increase of insanity that is supposed to exist.

### SOME "CAUSES" OF INSANITY.

Lectures to follow in this course will deal exclusively with the important and intricate subjects of causation and prevention, but there are a few aspects of the former which deserve mention here.

It is a common belief that a single circumstance, accident, shock, habit or tendency is the sole cause of a mental breakdown. We are asked what is "the" cause of a patient's insanity, as if but one factor were responsible for the condition. On the contrary, a number, a conspiracy of causes, have been at work in most cases. Disease-inheritance, poor nutrition and physique, hardship, poverty, alcohol, bodily disease, emotional strain, — especially anxiety, — exhaustion from physical or mental overwork, domestic troubles and misunderstandings, a succession of afflictions, mental conflicts, etc., combine in varying number and degree to produce the attack. For example, overwork in study is frequently given by relatives as a sole cause of an attack of mental disease in youths, while, in fact, it is almost never operative alone. Often anxiety over the expense of living and education, a bad heredity, poor nutrition, secluded habits, neglect of healthful exercise, recreation and association are factors without which the mental strain of close application to study could have been easily withstood.

Fright is popularly supposed to be a not infrequent cause of insanity, but in point of fact I have been unable to recall in my experience or the literature of the subject at my command more than a very few cases originating in this way. But while fright, shock or the accompanying stress only very rarely results in insanity, it is common enough as a cause of less profound and more purely nervous conditions, such as neurasthenia or "nervous exhaustion" (from railway accident, for example), hysteria, St. Vitus' dance, epileptiform seizures, etc. The same is true of any injury to the head which the patient may have had. This is frequently offered as the sole cause of cases of insanity, perhaps because of the fact that the same part of the body is involved in both, and some connection between the two is ignorantly supposed to exist. Without going into the reasons why this is seldom the case, the chief of which is the wide difference in the disease-processes of the two conditions, it is enough to say that only a very small proportion of cases of genuine insanity so originate,[4] while,

[4] Of 2,910 commitments to the Massachusetts State Hospitals during the year 1909, but 9 cases were classified as traumatic, i. e., due to injury.

on the other hand, head-injuries from falls, etc., are common occurrences.

There is also an ingrained but equally mistaken belief among people in general, especially womankind, that the climacteric or menopause is the principal cause of insanity, occurring between the ages of forty and fifty-five or thereabouts. Insanity is, to be sure, particularly prevalent in this decade, but not more so in women than in men. In fact, there are rather more men who become insane at that age than women. Competent opinion as to the baleful effects of the climacteric upon disease in general has, indeed, greatly altered in the last twenty-five years, and it is no longer looked upon as a time of life fraught with peril and difficulty. In insanity we should surely look deeper before ascribing to a single local physiological condition the importance of the entire upheaval.

Formerly, when less was known regarding the pathology of insanity, the physician too often confounded cause with effect, thereby spreading false impressions among the laity. A notable example of this tendency was the very general belief, which is still largely prevalent, that solitary sexual practices were directly responsible for mental breakdown in youth as a general rule, whereas the truth is that this enervating habit, when appearing in connection with an attack of insanity, is far oftener a symptom or result than a cause of the mental trouble and its importance as a cause of insanity is greatly exaggerated by people in general. Too often, also, the insane melancholiac freely accuses himself of disgraceful acts and sometimes even crimes which he never committed and are entirely foreign to his normal character and habits, but which some unthinking friend or neighbor is ready to believe and perhaps report as the cause of his breakdown.

Lest, however, the impression be left that insanity never has its origin in a single condition, a certain relatively small proportion of cases so arising must be mentioned. Paresis or general paralysis, whose newspaper term is "paralysis of the brain," and is frequently miscalled "softening of the brain," is in most cases the late result of a single toxic agent, syphilis, without which the disease would not occur. Typhoid fever, also, occasionally leaves the formerly strong and healthy young mind unhinged and sometimes irrevocably shattered. Influenza, pneumonia, scarlet fever, erysipelas of the head are now and then the direct and sole causes of mental disease. Alcohol may of itself produce a special form of insanity, and toxic conditions at childbirth are occasionally the direct and sole cause of puerperal delirium. Pellagrous insanity, also, is due solely to eating damaged maize.

### INSANITY NOT NECESSARILY HEREDITARY.

Faulty inheritance is such a potent element in mental disease that many people believe insanity to be always inherited from insane parents or other antecedents. It is surprising how general this belief is. Now, a bad family tendency of this kind may be shown in actual and marked insanity of certain members, while the rest are sound and strong and appear to have the normal amount of resistive power to disease, but this is a better inheritance than less distinct mental disease, more unsoundness and a low state of mental and bodily health in the family generally, in the forms, for example, of various nervous disorders, convulsions in childhood, low grades of mental capacity, bad habits and propensities, physical defects, a tendency to tuberculosis, etc., conditions from which insanity often springs. The fact is far too insufficiently recognized that "the factor that is directly inherited is not insanity, but an instability or disordered arrangement of nerve tissue which allows insanity to occur, and we must look for the heritable antecedents of insanity not alone in insanity, but in all maladies, mental and physical, which give evidence of undue irritability or disorder of the highest nerve arrangement." There are, it is true, certain forms of insanity to which inheritance gives a special stamp, but there are also many cases of mental disease in which no disease-heredity can be found and where the ancestry is apparently of sound and healthy stock. Paresis, for example, is an acquired disease which occurs very often in the robust and energetic in the prime and early middle of life. As regards this malady there is nothing worthy to be called proof that hereditary predisposition is a factor. It is nevertheless a progressive and fatal enfeeblement of the mind and body with marked insanity. Two hundred patients with this disease were admitted to the hospitals of Massachusetts, and one hundred and seventy-seven succumbed to it in the year 1909.

Dementia precox, the insanity of youth, which I shall describe later, the most common, the most important, the most baneful of all, usually springs from the soil of hereditary defect or instability, but in a fair proportion of cases variously estimated by different observers it may be simply acquired, i. e., occurring without any discoverable trace of insanity or allied disorder in the family history. This form of mental disease seldom appears after adolescence except as a second or still later attack, being practically peculiar to youth. In the last ten or more years it has been the subject of far more investigation than any other form of insanity, and an immense amount of work has been devoted to it. One result of this has been that it no longer holds the place that it once held as an exclusively hereditary disease. Many cases are found to have originated from exhaustion of the nervous and bodily strength through physical fatigue as the principal cause in persons of fairly good physique and average health. Rapidly growing youths or girls, particularly in the humbler stations of life, apprentices, clerks, train-hands, stable-boys, mill operatives, certain domestics, not infrequently succumb to the exhausting effects of hard physical labor combined with long hours, perhaps work "overtime," little sleep, insufficient food and, in consequence, disorder of nutrition. Insomnia and lassitude arise and mental break-

down follows, sometimes without the aid of any appreciable hereditary predisposition to insanity. If it should be present, this sad result is only the more rapid and more profound.

The fever of athletic competition has led many a delicate student, ignorant or careless of the laws of health, to such a depletion of his strength and vigor as to sap his mental and bodily stamina and thus to prepare the way for an attack of insanity. Nowadays there is no lack of incentive, training and apparatus for athletic effort; it is always close at hand and there is very little likelihood of poor physique and under-development occurring in the modern youth. The physical, moral and even mental advantages to the individual and the race resulting from athletic exercise have long been kept before us. Certain physical dangers following its abuse are, to be sure, gradually becoming recognized, but nowhere do we find proper appreciation of the influence of undue physical exercise as a factor in the production of mental breakdown in adolescence in the shape of dementia precox. I believe it to be of enough importance in itself to call for more general regulation, individualization and restriction of athletic exercise and competition than now prevails if we are to secure the best results in the hygienic protection and development of the youth of to-day.

### INSANITY AND THE MARRIAGE OF NEAR KIN.

The influence of heredity on disease is also responsible for the strong popular sentiment that exists in regard to the evil effects upon offspring of the marriage of near kin. This question has long been a battleground for the physician, biologist and sociologist, but it is now quite generally conceded, as a result of statistical analyses on a large scale, and the observations and arguments of acknowledged authorities, that the evil has been greatly exaggerated. Nevertheless it remains a common popular belief that insanity occurring in children of related parents, usually first cousins, is clearly due to the fact that they were of the same blood. In many minds this opinion is so deep-rooted that it cannot be dislodged. George Darwin's facts and figures, and Huth's exhaustive work on the marriage of near kin, not to mention the observations of Morselli, an authority on suicide, have had much to do with changing the old belief in the dire consequences of such marriages. The researches of Withington[1] are a valuable contribution to the question and show quite conclusively that the offspring of related parents are in no danger unless these parents are sharers in any family disease or tendency. Alienists of authority hold the same view, and although there are still exponents of the harm to follow from such marriages, the trend of recent opinion is decidedly in favor of our contention. To be sure, we occasionally hear of disastrous results in such cases in the shape of imbecile or otherwise defective children, but we are usually ignorant of their true family history as regards disease.

[1] Reference Hand Book Med. Sciences, vol. iii, p. 258.

It is, therefore, entirely safe and within the bounds of fact to say that marriage between cousins is only dangerous as regards insanity in descendents when they closely resemble each other in physique, in mind and general tendencies, or when there is an unmistakable taint of insanity in the common family. Otherwise no harm whatever is likely to come to the offspring of such a union under ordinary conditions.

### WHAT CONSTITUTES INSANITY.

The practical test of a person's insanity is not what he thinks but what he does. His fears, his promptings, his ideas are not insanity unless they are expressed in acts — in *conduct* endangering his safety, or prejudicial to his business success, his health or his family or social interests, or those of others. It is not enough that the mind alone be simply disordered. For example, a man in the full enjoyment of health may for most of his life entertain a fixed idea that his legs are made of glass and yet so long as he does not by speech or conduct let his belief affect his daily life, his business affairs or his attitude toward others, he cannot be considered insane. Should he, however, keep his bed for fear of breaking his legs if he should stand up, his insanity would be manifest. In fact, mental disorder without insanity is far from uncommon. "Psychasthenia," formerly known as neurasthenia, is often expressed in irresistible morbid fears of various kinds which the patient realizes are absurd, but of which he cannot rid himself. For example, fear of large open spaces, fear of dirt, of contamination from contact, etc., as well as doubts of various kinds. The trouble, in fact, was once classified as the "insanity of doubt." A lady, for example, experiences great agony of mind at the prospect of having to cross a large city square; a busy clergyman will not take a closed carriage even when caught in a storm because of the actual terror he experiences at being shut up in a small space and his desire to burst out of it; another washes his hands a great many times a day for fear that they may have touched some article or person carrying disease-germs. There are numbers of such persons who for their entire life, and others for a part of it, carry about with them such tormenting fears without disclosing them or allowing their dread to affect the performance of their usual duties or their attitude toward others, and no one is any the wiser as regards this mental state, for they are able to adjust themselves to all conditions of life. They act in harmony with their surroundings and society generally, and are, therefore, not insane, although suffering from a mental disorder. Occasionally, to be sure, some patient of this class is carried too far in his terror and becomes unsettled and even panic-stricken to such an extent as to do strange acts, neglect his business or to suffer in physical health and then to need medical care away from home for a time. These extreme cases have, during this stage, passed the border-line of sanity, although the trouble is of mild form and usually temporary. The fear of approaching insanity, due to ignorance of its mechanism, is

another mild, disordered, mental state which is rather common in sane people, usually during the anxiety attending or reaction following some distracting experience or season of nervous ill-health, especially in those who have once had an attack of mental disease or who can find signs of such disease in the family history. The dreaded attack only rarely follows such a mental state and as a rule we are safe in assuring such persons that the fear of insanity is by no means a sign of its approach.

Not only are these minor degrees of mental disorder that I have mentioned within the borders of sanity, but actual hallucinations, that is, sense-perceptions without any external object being present — a condition that is very common in actual insanity — are not always indications of insanity, especially when recognized by the mind as hallucinations, and occasionally not even then. Instances are not rare of persons who firmly believed in the reality of some single hallucination while having no other trace of mental disease, and preserving all their correctness and vigor of mind. Martin Luther always believed that the devil visited him in his study and in his bed, that he saw him with the bodily eye, and heard him with the bodily ear. Dr. Johnson heard the voice of his mother calling to him, "Sam! Sam!" though several miles away. Rapp, one of Napoleon's generals, says that on entering the Emperor's cabinet on one occasion he found him so abstracted and self-absorbed that he feared he was ill. When, at last, he attracted the Emperor's attention, he told him to look up. "Do you not see her?" he said. "She is before you bright and brilliant. She has never abandoned me. I have seen her on every great occasion. She tells me to go on and she is always the sign of good fortune." Cromwell was fond of relating in the days of his power that, when at school, a woman of gigantic height drew aside the curtains of his bed and announced to him his future greatness. Lord Castlereagh, while visiting a friend in early life, saw at night, before going to sleep, the vision of a radiant child with a glory circling his head. He saw it again many years afterwards in the House of Commons.[6]

Similar examples might be multiplied indefinitely, but enough has been said to show clearly that disorder of mind, including both disorder of thought and feeling, may exist without insanity. In actual insanity mental disorder cannot exist alone; disorder of *conduct* must also be present. As Mercier puts it, "Their co-existence implies and necessitates disorder of those highest nerve processes which actuate the one and accompany the other. . . . It is the conduct, the way in which the individual adapts himself in ways large and small to the circumstances which surround him, that is the essential factor in insanity and gives it its whole significance. . . . In short, if we discover a mental disorder and find that it has no influence upon conduct, we cannot regard it as an evidence of insanity."[7]

[6] Ray's Medical Jurisprudence.
[7] Mercier: Sanity and Insanity, p. 104, etc.

There is an absurd and favorite saying that every one is more or less insane because all of us know that there is no man who at times is not unnecessarily depressed, excited or "queer," or loses his control without adequate cause. Such a popular belief is very unfortunate because it is utterly erroneous and confuses the public mind on a most serious problem. We might as well say that every one is more or less of a physical invalid because no one is perfectly sound in all his organs and other parts of his body under all conditions and at all times; in other words, that no one is physically perfect. To say also that every one is insane on "some point" is equally absurd. It is as ridiculous as to say (to again quote Mercier[8]) that everyone's digestion is disordered on some point. No doubt there are for every man circumstances to which he cannot adjust himself, just as there are things which he cannot digest, but the fact that he cannot always adjust himself to his circumstances is of itself no more proof of insanity than the fact that he cannot digest tenpenny nails is of itself a proof of disordered digestion.

### DISTURBED PATIENTS.

It is still quite generally believed that there are large numbers of highly excited and turbulent patients, or "raving maniacs," in our institutions. This is a remnant of the old opinion that insanity always meant an entire dethronement of reason and self-control and consequent frenzy. It will surprise any who may still hold such a belief to know that, at the Taunton State Hospital in Massachusetts, for example, there were, at the time of writing, but 57 out of the entire number of 945 inmates who are classed as excited, 97 as dangerous and 35 who are both excited and dangerous cases. The rest of the patients are quiet and amenable but require to be in confinement because, in consequence of their mental condition, they unsettle their families and neighbors by strange or obstreperous propensities or endanger their own lives or neglect themselves and their bodily wants, etc., and need the special medical attention and supervision that an insane hospital affords. Most patients of this class are quiet and well-behaved; many show average intelligence on ordinary subjects and are often good company, and a few have more than ordinary mental endowment apart from their morbid ideas. A certain number are to be found in every such institution who have practically recovered but who only remain well so long as they are leading the sheltered and restricted life of a hospital. The moment they are at large they relapse into their old mental condition owing to their inability to adapt themselves to the simplest conditions of outside life.

### VARIETIES OF MENTAL DISEASE.

It is surprising how many people there are who think that insanity is all one disease, when in reality it has, like bodily disease, many fairly distinct forms and varieties, each having in the

[8] *Ibid.*, p. 131.

main its own peculiar features. In the statistical tables compiled by the Massachusetts Board of Insanity, thirty-three forms are listed. By these I do not mean merely mental states or symptoms such as apathy, confusion, stupor, excitement, depression, suspicion, delusions, obsession (i. e., besetment), irresistible impulse, childishness, moral perversion, etc., but the regular varieties of mental disease, namely, idiocy, imbecility, dementia, confusional insanity, delirium, manic-depressive insanity (i. e., alternating attacks of mania and melancholia with rational intervals or a periodical manifestation of either kind alone), involutional melancholia (i. e., melancholia coming on in people who are passing or have passed middle life, a presenile state), senile dementia, alcoholic insanity, toxic or drug insanity, moral insanity, paresis, epileptic insanity, insanity associated with organic nervous disease, etc. Time will admit of but the briefest sketch of a few of the most important of these forms, and to do justice to the subject would necessitate technical descriptions which are out of place in a Popular Lecture.

The true idiot is, generally speaking, one born without a mind, one who never develops much more intelligence than a normal infant. The imbecile, however, once had the beginnings of a mind in infancy or early childhood, but its development has been arrested by a head injury, it may be, or severe fever of some sort. The weak-mindedness of the latter is of a higher grade than that of idiots, and some few are surprisingly near the normal. At the other extreme they cannot be distinguished from the higher order of idiot. But, however high in the grade of intelligence the imbecile may be, he is never able to earn his own livelihood. People in their dotage and those who have become weak-minded from mental disease are often erroneously called "imbeciles" when their real condition is one of dementia.

By far the largest number of insane persons are "dements," so-called, i. e., cases of dementia, by which is meant a *loss* of mental power of greater or less degree as distinguished from the simple *perversion* of the mind found in other forms of insanity in which there may be no loss of mental strength and activity. Dementia is the weakened, inactive and more or less helpless condition which underlies and follows acute insanity. It is the essence of dementia precox, senile dementia and the dementia which results from organic brain disease, i. e., from paresis, apoplexy, softening of the brain or tumors and other brain diseases. The latter are called "organic" because of the breaking down and disorganization which takes place in the substance of the brain itself, in distinction from "functional" insanity, such as mania, melancholia, paranoia, etc., in which no change in the tissue of the brain is discoverable after death.

The principal form of dementia is dementia precox, of which I have already spoken. This is the disease which takes the form of mental breakdown in adolesence, the period of life which, next to old age, is by far the most critical. It occurs in youths of a certain mental makeup and at any age between fifteen and twenty-five or thereabouts, only a few cases originating after thirty, and is the most common of all forms of insanity. Six hundred and thirty-two patients, or about 25% of all cases admitted to the Massachusetts insane hospitals in 1910, suffered from this kind of insanity, and the majority of the chronic cases remaining in our institutions are the mental wrecks resulting from this variety of mental disease. Its underlying condition throughout is gradual enfeeblement of the heretofore normal intellect, a slow decline of mental power and activity. This may be and usually is obscured in the early stages by periods of excitement and violence or melancholy with suicidal tendencies, hallucinations and delusions or confusion or ideas of persecution. Sometimes there exists profound stupor, in which the patient is more or less oblivious to all external impressions and frequently remains motionless in some peculiar attitude. It ends generally after a few years, with short intervals of apparent recovery, in a state of permanent degeneration of mind of greater or less degree and extent, but which in most cases involves the mind in more or less complete and permanent disorganization, making constant hospital care necessary, as a rule. A few cases, 13%, apparently recover. Another small proportion stop short of extreme loss of mind and live in considerable comfort, satisfaction and even enjoyment a life similar to that of high-grade imbeciles.

Manic-depressive insanity, otherwise known as alternating and periodical insanity, is characterized by the recurrence of mental disorder in the form of mania, or melancholia, alone or replacing each other, in distinct periods. The attacks are separated by intervals which are more or less regular during which the mind is practically as sound and clear as ever. Sometimes the mental condition is maniacal excitement or great restlessness, sometimes melancholia, or, one of these states may immediately succeed the other, an interval of rationality following which may last for years. Some cases have a regular cycle, within a year or two, of excitement or exhilaration, passing, without break, into profound depression, which in turn emerges as suddenly into rationality. This latter form is called circular insanity.

Paranoia is a chronic form of insanity based on an acquired or inherited degenerative taint and manifesting itself in false ideas of injustice, suspicion and persecution — delusions which often result from the non-recognition of the patient's supposed importance or abilities and overbearing egotism. Delusions and hallucinations of hearing — the so-called "false hearing" — usually develop sooner or later, but the patient's reasoning power outside of his delusions may be acute and logical. The delusions which are sometimes cleverly concealed become fixed and are usually of a disagreeable kind. The patient may be persecuted by "voices" conducted to his ears by electricity in some mysterious way. People "read his thoughts." Paragraphs in the news-

papers refer to him. He is haunted by detectives, Free-Masons or Roman Catholic priests. Sometimes hallucinations of smell and taste are present. In his search for the cause of his persecution he fastens upon some person or persons about him whom he is likely to assault or annoy in some way. The most dangerous insane belong chiefly to this class. Not infrequently the paranoiac in his determination to obtain justice for his supposed wrongs fastens his delusions upon some one in authority because of his power over others, himself included, and accuses and villifies him. Sometimes he goes farther and attacks him and perhaps takes his life. Any person at hand, even a stranger, may become his victim. Steele, for example, whose murderous assaults at the State House in Boston a few years ago will be recalled, was a pronounced paranoiac and committed the act in order to secure a trial, in the belief that it was the only means left by which he could bring the innumerable persecutions practiced upon him to public attention and secure redress and protection. Patients of this class are sources of constant trouble to hospital officials by their persistent and sometimes plausible but nevertheless false accusations of personal maltreatment and neglect and mismanagement of the institution in which they are confined. True paranoia is not a common disease, but comes oftener under public notice than other forms on account of the dangerous acts by which it is often manifested.

Paresis, that important and grave disease, is, in the great majority of cases, one of the late after-effects of syphilis and results in degeneration and wasting of certain portions — chiefly the gray matter — of the brain. It is most frequent between the ages of thirty-five and forty and is marked by a combination of mental and bodily symptoms. The disease tends to increase more or less steadily and is practically always fatal, hospital patients usually dying in from two to three years. There is a gradually increasing enfeebling of the mind with slow extinction of the memory and the intellect generally. Often there are periods of more or less intense excitement, delusions of great power and wealth, restlessness and propensity to hoard rubbish. Frequently there is no especial excitement, but extreme depression, and hallucinations of hearing are prominent. The accompanying bodily affection consists in a very gradual paralysis which usually affects at first the lips and speech and gradually extends over the whole body until the patient becomes utterly helpless. Convulsive seizures of the nature of epilepsy and apoplexy are common in the course of the disease. This is a form of mental disease which is steadily increasing with the advance of civilization and is comparatively rare in primitive and barbarous races.

Uncomplicated melancholia, occurring as a rule after the changes of senility have set in, is known as the "anxiety psychosis." It is characterized by deep despondency, often extreme agitation and anguish due to strong delusions, usually of wrong-doing or of extreme destitution, and forebodings of suffering and torture. No more intense pain can be suffered than the prolonged and sometimes uninterrupted day and night agony of some of these patients in the early months of the disease. A certain portion recover after a year or two, but are rarely able to completely resume their former activities. Their after-life is apt to run on a lower plane of energy and is considerably restricted.

### CHANCES OF RECOVERY.

The prospect of recovery from insanity is a subject about which there is much misinformation. In fact, a surprisingly large number of people still think that the insane never get well! Thurnam's statistical researches of many years ago on this subject never have been equalled for thoroughness and reliability. He followed up the histories *until death* of the patients treated at the Friend's Retreat near York, England, during a period of forty-four years, and his estimate of the prognosis of insanity from these data still holds good in the main. He wrote, "In round numbers, of ten persons attacked by insanity, five recover and five die sooner or later during the attack. Of the five who recover, not more than two remain well the rest of their lives; the other three sustain subsequent attacks during which at least two of them die." That is, there are under the best conditions about 20% of permanent recoveries.

Although this picture is an unfavorable one, it is very far from justifying the popular prejudice that insanity is virtually an incurable disease, and the view which it presents is much modified by the long intervals which often occur between the attacks, during which intervals of mental health — in many cases of from ten to twenty years' duration — the individual has lived in all the enjoyments of social life.[9] Moreover, such statistics are open to the great objection that they represent only hospital cases which are most likely to be of the severe, difficult and incurable variety. They cover, therefore, but part of the ground, and a much different idea of the prospect of cure would prevail if the undoubtedly large number of cases, chiefly of melancholia, which recover without going to a hospital or even to a doctor, could be included. In reply to an inquiry instituted by the Massachusetts State Board of Insanity,[10] 685 physicians of that commonwealth stated that of the 2,428 cases of mental disease treated by them during the year 1904, but 55% had been committed to an insane hospital, while 38% had been treated at home and the rest elsewhere outside of institutions for the insane. This tends to show that there is a large contingent of cases, a fair proportion of which are presumably of the milder and curable forms of insanity, which is not sent to hospitals.

It is a common belief among non-medical people, and to some extent among physicians, that mental disease when plainly inherited involves impossibility of recovery in any degree

[9] Earle: The Curability of Insanity, p. 60.
[10] Sixth annual report of the State Board of Insanity (Mass.), 1904.

from an attack of insanity. On the contrary, so far as the attack goes, certain strongly hereditary cases make good recoveries, although they are more liable to relapse than those in which the hereditary taint is absent or slight.

DURATION OF INSANITY.

"How long does an attack of mental disease last before recovery?" we are frequently asked. Its duration may be approximately stated as within three months for 25% of all recovered cases; less than six months for 50%; less than a year for 75%. About 20% of all recoveries are from insanity of over a year's duration.

THE EFFECT OF CARE AND TREATMENT.

The remark once made to me by a prominent surgeon, that when a person recovers from insanity "he gets well of himself," well represents a much mistaken but not uncommon sentiment regarding the care and treatment of the insane — that in this, unlike other diseases, medical interference has little effect in curing the patient. Now, as a matter of fact, this is not a whit more true of mental than it is of most physical disease in which recovery has taken place. In bodily maladies, however, there is abundant opportunity to follow the symptoms, course and treatment of the case — to observe the patient close at hand. The family of the patient, the friends and the neighbors perhaps, if the patient be at home, and many others if he be treated in a hospital, know in detail just what has been done for him and how his case has progressed. His recovery, therefore, is naturally recognized as the direct result of appropriate medical treatment. In mental disease, on the contrary, only the result and very rarely the steps taken to reach it are known, for most insane patients, from the nature of their disorder, must be treated away from home or in the utmost seclusion, even the bare fact of their illness being concealed so far as possible. If bodily disease were treated under these conditions, how long would people hold their faith in the physician as a healer?

Let me give you some idea of the work of the modern hospital alienist. He first satisfies himself as to the true nature of the patient's trouble by inquiry of his relatives into his natural mental make-up, his history, mode of life and the intimate causes of his disease, and by a careful analysis of his condition by personal examination. Then, as a part of his daily routine, come the protection of the patient from disturbing influences and from tendencies harmful to himself and others; the support of his strength against exhaustion by proper food — sometimes artificially administered; the production of quiet of mind and sleep by baths and other sedative measures; the upbuilding of his nutrition and strength by tonic treatment and systematic exercise; the arousing of the sluggish and the diversion of the depressed mind by occupation, amusement and, if need be, by change of surroundings; repeated explanations and encouragement given the patient with delusions, etc. All this requires constant and untiring trial of various expedients and unceasing and often anxious vigilance. This is purely medical treatment conducted on the same general lines that are followed by the physician in treating physical disease and is plainly quite as likely to influence the recovery of the patient. It often requires, moreover, a degree of special training, insight and knowledge of the individual and of human nature which is seldom called for in the conduct of a case of bodily illness. Nevertheless the alienist's work is practically hidden behind hospital walls so far as the public is concerned, and people in general know little of the care and treatment of the patient except when a suicide, an escape or other accident, or a reported abuse directs hostile attention to the institution in which it occurs.

Another lecture in this course will be devoted to descriptions of institutions for the insane and the various methods employed for their care, treatment, occupation and diversion. You will also be told of the training-schools for nurses and the pathological laboratories to be found in most hospitals of the kind, as well as the colony, the family or boarding-out systems and the after-care associations that are in operation. It is only by disseminating such information in popular form that we can hope to overcome the lamentable ignorance regarding insanity and the prejudice against hospitals for the insane that are still so general, in spite of the great progress that has been made toward ameliorating the lot of those unfortunates.

It is surprising to find how many people there are whose ideas of the care of the insane in hospitals are formed or largely influenced by exaggerated, if not fictitious, newspaper reports of the abusive treatment of this or that patient, occurrences which cannot always be avoided where large numbers of the insane must be treated together. Such accounts of very exceptional happenings not only subject the medical and nursing staffs of the many well-conducted hospitals to unwarranted misrepresentation and reproach, but, what is worse, cause the relatives and friends of the inmates untold uneasiness and often great anxiety.

There remains, of course, much to be learned and to be done toward advancing the knowledge of the disease, safeguarding the welfare of the patients and improving and extending the various provisions for their diversified needs, and it should be borne in mind that, although these problems do not meet the notice or create the interest that is attracted by other medical questions, they are none the less important and their solution requires and receives the same degree of scientific thought and effort.

THE Texas State Department of Health has been advised that yellow fever has made its appearance in Mexico. An effective quarantine against the infected places is urged. — *Med. Rec.*

## Address.

### ADDRESS OF THE PRESIDENT BEFORE THE NEW ENGLAND PEDIATRIC SOCIETY.*

BY JOHN LOVETT MORSE, A.M., M.D.

IT seemed to me that it would be of interest at the beginning of this, the fourth year of the New England Pediatric Society, to review rapidly the past history of the society and to plan a little as to the immediate future. The society was founded Jan. 4, 1908. The original members numbered between forty and fifty. The membership at the end of the first year was 93, at the end of the second year 109, and at the end of the third year 122. This number is large enough to make a flourishing society. It would be better, however, if we had twice this number. We can easily have it if the individual members will aid the officers in getting new members. In the past this matter has been left almost entirely to the officers, who have done yeoman service. If every member would get to work and bring in at least one new member, the size of the society would quickly be doubled. Personal solicitation is very important in this connection, as nobody ever pays any attention to a general invitation. It would seem as if there was a large field for this society in New England, because the subject of pediatrics is one which should appeal to every general practitioner. It is a subject which should interest him almost as much as it does the specialist, since a large part of every general practitioner's work is among children.

The average attendance in 1909 was 36, or 33% of the membership, while in 1910 it was 36, or 29.2% of the membership. The smallest number at a meeting last year was 23, the largest 50. This is not a bad average. It ought to be better, however, when the standard of the meetings is taken into consideration. This standard is very high, fully up to that of the meetings of the national societies. There has been no meeting since the foundation of the society which it would not have been profitable for every one, whether a specialist or not, to attend.

The standard of the meetings is, as I have already said, very high. It is not so high, however, but that it can be improved. It would be hard, nevertheless, to raise the standard of the papers, as they are already so good. There are certain suggestions, however, regarding the papers, which I think would improve them. One of these is that a short paper is always more interesting and more instructive than a long one. There are often many details which should be published, but which are tiresome and are better omitted when a paper is presented to the society. Another suggestion is that papers are always more impressive and more interesting when they are spoken than when they are read. This method of presentation is, of course, harder than the reading of a paper, but the gain in interest is well worth the additional trouble. It is always well to remember that the details of cases, and especially pathological details, are always tiresome and usually unnecessary, and that they can be printed and read later at leisure. It is impossible, also, for a listener to grasp long series of figures or statistics. They should be presented in the form of tables, or only the main points given.

The discussions have not been free enough in the past. The members have apparently been afraid to talk freely for fear that they would hurt somebody's feelings if they disagreed with them. This seems to me to be entirely wrong. As competition is the life of trade, so free discussion is the life of a medical meeting. Every one ought to be man enough not to be offended when some one disagrees with him in a medical meeting, and not to carry away any ill feeling from the meeting.

It has seemed to me that rather too much time has been given in the past to the reading of papers and too little to the presentation of patients, pathological specimens and short case reports. I feel sure that all of these matters would be of interest and add variety to the meetings.

It would be a great help to the officers if the members would volunteer to present papers, patients or specimens, and not leave it entirely to the officers to drum them up.

The constitution says that three or more meetings shall be held annually. Four meetings have been held in each of the last two years. I hope that it will be possible to hold more than this during the coming year. Whether it will be possible or not depends, of course, on you; that is, on whether you are willing to provide the material for the meetings. With your assistance we can have more meetings and better meetings. Without it we cannot.

## Original Articles.

### WHEN SHALL WE REMOVE TONSILS AND WHAT TYPE OF OPERATION SHALL WE DO?*

BY EUGENE A. CROCKETT, M.D., BOSTON.

THE question of when to operate on tonsils, and what class of cases on whom to advise operation, is a very vital one in modern practice. Judging from cases that I frequently see in consultation, it may be said that many times the removal of children's and adults' tonsils is advised for very insufficient reasons and without apparently regarding it as a critical operation. One has only to look over an instrument catalogue for the past year and see the rapid increase of new instruments designed to check tonsil hemorrhage to realize that the removal of tonsils is often an operation of considerable severity and very considerable risk. In fact, as far as the occurrence of serious accidents and fatal results go in its performance in and around this city, it must be acknowledged that in unskilled hands it will show a higher mortality than an abdominal operation for interval appendix in the hands of a good surgeon.

* Read at the thirteenth meeting of the New England Pediatric Society, Jan. 28, 1911.

The occurrence of twelve deaths in this city and its suburbs in the last year and a half or two years following upon the removal of tonsils, as well as the occurrence of a large number of very considerable hemorrhages also fatal unless checked by experienced hands, would prove to my mind that it is not wise to advise such removal except on sufficient symptoms.

On looking over the literature, a wide difference of opinion is seen to exist among the physicians of this country, many of whom seem to regard the tonsil as the root of all medical evil to a degree unjustified by the facts. Take, for instance, in the question of rheumatism. While it is beyond question that a patient with a large tonsil full of cheesy concretion and subject to repeated attacks of acute tonsillitis is liable to an acute nephritis and also to acute articular rheumatism by reason of the existence of such throat condition, yet it does not follow that the tonsil is the whole cause of acute articular rheumatism, neither does it follow that the patient on whom a complete enucleation has been performed may not still have an acute infection of the throat with follicles on the pillars and lateral pharyngeal wall, which is certainly clinically tonsillitis if not actually so. On the other hand, I fail to see why a person possessing an approximately normal tonsil, I mean one that does not project far beyond the pillars of the pharynx, who presents no history of throat infection other than perhaps a single attack of tonsillitis or an occasional pharyngitis, would be much less liable to acute articular rheumatism from removal of these normal tonsils. As far as my own experience goes, acute rheumatic infections are certainly just as commonly associated with acute and chronic infections of the maxillary sinus or the sphenoidal sinus as they are with acute infection of the tonsil, yet it is certain that no one would advise the radical opening of the normal frontal sinus for relief of rheumatic infections which might possibly occur in the future.

Why, then, should we advise the removal of a normal tonsil for the same reason?

Then as to the question of glands in the neck, tubercular glands. We know from a large series of statistics that somewhere between eight and ten per cent of operated tonsils show evidence of tubercular infection. Such tonsils do not differ macroscopically from the usual hypertrophied tonsil. A much smaller proportion of cases are accompanied by glands in the neck. It is proven beyond dispute that the group of glands just in front and just behind the sterno-cleido-mastoid muscle when tubercular are nearly always associated with disease of the tonsil, receiving their infection through it.

From the clinical standpoint there is ample warning of such condition occurring in the neck, and as far as my experience goes the removal of the infected tonsil within any reasonable length of time of beginning glandular infection of the throat will serve to remove the cause of trouble before the throat becomes infected to an operative extent. Here again it is impossible to make a clinical diagnosis of tubercular infection of the tonsil in a large proportion of cases, and its association with tubercular glands in the neck is a relatively rare occurrence. I contend that here also it would be absolutely unnecessary to remove a reasonably normal tonsil with no history of infection on a pretext that we should avoid a tubercular process in the glands of the neck.

However, in passing, having criticised freely the shortcomings of my own specialty, I would like to say that the general surgeon who treats glands in the neck is remiss also if he does not consider the probable origin of the infection in the tonsil and remove the tonsil at the same time as the glands, or at the first opportunity afterward.

To try and summarize and reduce to a definite statement the class of cases which one believes should be operated on, I should say that in children one should remove the tonsils in all cases where the child presents large non-adherent tonsils largely filling the cavity of the pharynx because of the obstruction in breathing that such cases present and of their possible influence upon nutrition, and to secure the proper formation of the jaw at the period of second dentition.

Second, one should enucleate the tonsil in all cases where associated with enlarged glands in the neck, and in all cases of articular rheumatism where the tonsil is probably an etiological factor. These operations should be, as a rule, performed in a quiescent period, especially in the case of rheumatism, when the nervous shock and the additional sepsis should both be avoided in the acute stage. The existence of endocarditis in a more or less chronic state need not necessarily be regarded as a contra-indication for operation.

Third, the tonsils should be thoroughly enucleated in all cases of repeated peritonsillar abscess.

Conversely, the tonsils should not be removed where they are of moderate size, I mean by that, projecting not over a quarter of an inch beyond the anterior and posterior pillars. They should also not be removed under the promise to the parents that their removal will relieve the child of cold in the head or ear trouble. This may seem a self-evident proposition, but my experience is that the parent is frequently assured that the operation will relieve both of these troubles, which is a result not to be expected.

In adults we occasionally see one or both tonsils very large, almost filling the pharyngeal cavity, with a history of repeated throat trouble in childhood, but with no throat infection for many years. I saw such a case about two weeks ago in a girl of twenty-two with a beautiful mezzo-soprano voice of grand opera caliber. She had had no symptoms referable to her voice for twelve years and had no voice fatigue on sustained effort. Such a case, and it is a fairly common one, would be anything but benefited by an operation. I think it should be remembered that the operative shock to the adult is very considerable. There is also the danger of hemorrhage, which is certainly a more considerable one in adults than in children. There is also the possibility in cases of persons with a well-developed musical voice that the

voice may be permanently injured or they may have to change the whole musical method to obtain the same good results, so that even although some tonsils are distinctly pathological, I do not advise their removal. With this exception my position would be the same, as far as indications go, both for children and adults.

I am quite sure that in doing an adenoid operation a great majority of operators remove all the tonsil tissue in the throat regardless whether it is normal or abnormal in amount at the time the adenoid is removed. This is a particular point which I wish to bring out, which is contrary to good surgical procedure. It adds a great deal to the amount of shock which the patient receives and does not add anything to the success of the operation, although materially increasing the danger. The mere fact that the child is under ether for an adenoid operation should not be considered justification for the removal of tonsils if they are of normal size and the case has no history of their infection.

If we have decided to remove the tonsil, what type of operation should we perform?

If the case presents a clear history of infectious process such as peritonsillar abscess, acute articular rheumatism or tubercular infection of the neck, beyond question the whole tonsil should be enucleated and removed as completely as possible. This should be done by blunt dissection rather than sharp dissection. The particular method which I follow is to incise the tissue between the tonsil and anterior pillar with a right-angle blunt-pointed Leland tonsil knife; a blunt dissector is then passed in this incision and swept up and down, thus separating the tonsil from the anterior pillar. The dissector is then passed over the top of the tonsil, at which point the operator should be careful to remember that the upper level of the tonsil is considerably above that of the velum palati. The dissector is then carried down between the tonsil and posterior pillar, but no traction is made upon the tonsil during this dissection. The Farlow tonsil snare is then threaded with a No. 5 steel wire and passed over the tonsil, the tonsil is seized with a lock vulsellum forceps and drawn well forward free of the pillars and the snare drawn home either gradually or rapidly.

Of course this is not the only method of removal of tonsils, but I think it is safer in the hands of the average operator than dissection with the sharp scalpel or sharp scissors, and it removes the tonsil as thoroughly as any method I have ever seen. From the use of this form of operation I have only had three post-operative hemorrhages in the last five years, of which only one was serious and none were fatal. This operation of complete enucleation is, however, only necessary for cases which show definite indications for its use. In an ordinary case of simple hypertrophy devoid of symptoms, the most common type in children, it is not necessary to remove the base of the tonsil, but a perfect result may be obtained by removing enough of the tonsil to bring it down to a normal size so as not to project beyond the pillars. This may be done with a snare or punch or with the tonsillotome, if the operator is more skillful in the use of that instrument than I am; personally I am always afraid of it.

We should, however, guard ourselves against future trouble by warning the parents that it is possible for the child to have an acute infection of the nasopharynx without the existence of any demonstrable amount of tonsil tissue, although the child is very much less liable to such infections than before the tonsils were removed. We should also after this type of tonsil operation keep the child quite quiet for several days, and particularly in cases of adults warn the family that there is going to be a very sore throat. In cases of adults, put it still stronger; always tell them they are going to have the worst sore throat they ever had in their life for a period of from four days to ten days after the operation. In children this period is usually from three to four days; in adults, more often eight to ten. By treating the case during this period as one who has been subject to a moderately severe operation, many of the after complications can be avoided. If this precaution is not observed, an occasional mild septicemia will follow the operation.

I now come to the portion of my paper which is the most difficult of all to handle with a due regard to the medical proprieties, namely, what class of operators is justified in attempting this class of operation. Perhaps before I go any farther I had best enumerate the particular accidents which have come to my attention in the last three or four years and which will perhaps serve to emphasize the point which I earnestly desire to make, — that the enucleation of the tonsils is a decidedly serious operation and not one to be undertaken lightly by everybody and anybody.

The particular accidents of which I have been personally aware have happened in the hands of men not used to general surgery, to say nothing of special surgery, but a few have occurred in the hands of experienced operators. They are as follows:

Two cases of immediate fatal hemorrhage of the throat with death in about two minutes following sharp dissection of the tonsil with a knife.

One case of severe hemorrhage in the throat following sharp dissection with scissors relieved by ligation of common carotid artery.

One case of death from strangulation from inhaled vomited material, the operating physician being unprepared for such an accident and, therefore, unable to do a tracheotomy.

One case of death apparently from anesthesia, possibly a case of enlarged thymus.

One case of slow hemorrhage from both tonsils following a sharp dissection partially checked by the use of the Mikulicz tonsil clamp, but then followed two days later by hemorrhages in the skin and pneumonia with death. This case I personally saw in consultation, although I did not operate on it. It was apparently hopeless from the start.

We have had at the Massachusetts Charitable Eye and Ear Infirmary within the past year one death from hemorrhage and three cases where it was necessary to ligate the tonsil pillars for the relief of severe hemorrhage, and two cases where a secondary hemorrhage was checked by the use of the tonsil clamp. I do not know how many accidents there were in other services, but these cases of hemorrhage would have died had they not received proper and prompt surgical attention.

There have also been two cases of ether pneumonia, one of which unfortunately was one of my own private cases, and it was followed by empyema, acute mastoiditis, acute meningitis and death.

This list of accidents comprises only the cases that have come to my own personal knowledge in consultation and otherwise. They bring me to a conclusion, which, while it may be misunderstood, I think should be said by some one, namely, that any operation in the throat requiring the use of general anesthesia is too dangerous a procedure for any one to perform who is not thoroughly competent to meet the surgical emergencies which may present themselves. These, as shown by the above list, comprise the ability of the operator to ligate the common carotid, to ligate the tonsil pillars, to do an emergency tracheotomy, also to perform artificial respiration. Unless the attending physician is able to do these things he is taking a great moral responsibility upon himself when he undertakes to perform any throat operation under anesthesia.

I am happy to say that in the deaths that have occurred in and around the city in the last one or two years, nearly all have occurred in the hands of men unaccustomed to surgery and its complications. Only one out of twelve occurred in the hands of an experienced operator, or in the hands of one whom I would consider an experienced operator.

This makes the moral of this paper still more marked, — not to operate without due deliberation and on definite indications, and during the operation remember the surgical landmarks of the throat. Remove the tonsil by careful blunt dissection, and having operated, treat the patient as a serious case for the next three or four days. Do not operate unless you are able to meet the necessary emergencies which every surgeon must expect to have occasionally. If these rules are observed, the operation will be undertaken with a minimum of bad results and a maximum of success from the standpoint of the patient and his family and will not be so generally performed as at present.

---

It is stated that the British South Africa Company has decided to appoint a special commission to investigate the sleeping sickness in Rhodesia. The commission will consist of Dr. Aylmer May, of Northern Rhodesia; Dr. A. Kinghorn, of Liverpool; Mr. H. Leach, of Northern Rhodesia; Mr. O. Silverlock, entomologist, and Mr. Jollyman, bacteriologist.—*N. Y. Med. Jour.*

## SECONDARY EFFORTS TO HASTEN HEALING AFTER MASTOIDECTOMY.*

BY E. O. REIK, M.D., BALTIMORE, MD.,

*Associate in Ophthalmology and Otology, Johns Hopkins University, and Surgeon in the Baltimore Eye, Ear and Throat Hospital, Baltimore, Md.*

In a recent number of the *Annals of Otology, Rhinology and Laryngology* (September, 1910, p. 539) Professor Mygind, of Copenhagen, discussing the post-operative care of simple mastoid wounds, makes the following statement: "As regeneration is very slow, even in cases of simple resection, I have several times, about ten to fourteen days after the operation, when the swelling of the soft parts had entirely subsided, curetted the whole cavity slightly and allowed it to fill up with a clot of blood and then made secondary suture. These experiments have given most encouraging results, the after-treatment in the majority of cases being considerably curtailed. If secondary suture is not performed, the after-treatment in cases of simple resection is, as a rule, of very long duration (on an average two and three-fourths months)."

During the course of Professor Mygind's visit to this country I had the privilege of spending several days with him, and the very great pleasure and profit of intimate talks with him upon various otologic topics. Among other things we, naturally, discussed the primary healing of mastoid wounds and the after-treatment of our failures in this direction, and we were mutually surprised to find that we had been working to the same end along the same lines. So far as I know, he has published but this one brief paragraph relating to the matter, and I am not aware of any one else having written about the measure which I desire to lay before you for consideration to-day.

It would seem to be superfluous for me to say much before this audience regarding my interest in the primary healing of mastoidectomy wounds; most of you have probably heard me dilate upon that subject before. Suffice it to say that I am quite as enthusiastic as ever about my work in that direction; that in the majority of my operations for the relief of mastoiditis I endeavor to procure primary union under the blood-clot dressing; that I succeed in a large percentage of these efforts; and that I again heartily commend the method to your favorable consideration. Be it understood, then, that in making the suggestion I am about to offer for shortening the period of convalescence after mastoidectomy I am *not proposing a substitute* measure, but rather an *alternative* for those who are unwilling to adopt the first plan, and a *secondary* measure for those whose first efforts at primary union fail.

I have always recognized the fact that a certain number of surgeons honestly feared to attempt closure of the mastoid wound, and that to them all efforts to secure primary union appeared to be dangerous.

I must assume that these surgeons are quite as anxious as am I to shorten the period of conva-

* Read before the Eastern Section of the American Laryngological Rhinological and Otological Society at Boston, Feb. 4, 1911.

lescence and reduce to a minimum the post-operative treatment and, as several others have done, I have given some consideration to the question whether any modification of the advocated technic could secure at the same time a wider adoption of the method and the desired operative results. Such modifications as have been suggested have not appealed to me because they were either in no sense important modifications, or they prevented the possibility of primary union; it is a case of trying for primary union or else packing the wound for slow granulation; to my mind there is at that time, the conclusion of the mastoid operation, no middle ground unless the alternative plan which I shall describe may be so considered.

I have chosen, as a general rule, to try for primary union, and you know with what results, — approximately 75% of successes, — though I have not selected the cases to be subjected to this form of dressing and have eliminated very few as unfit or unsafe. But the fact stands out that even the most earnest advocate of the plan sometimes fails; that no matter how careful one may be, primary healing does not necessarily follow in every case; and this has led me to the second reason mentioned above for writing this paper, — a recommendation as to secondary efforts to hasten healing.

With the cordial aid of my assistants I have studied my cases in search of an explanation as to why some cases heal *per primam* and others break down. We have found some reasons that apply broadly to all cases and have discovered some special reasons applicable to individual cases. It goes without further saying that without aseptic preparation and operative technic approaching perfection success cannot be expected. Likewise, a complete operation, thorough eradication of the necrotic bone and inflammatory products is essential to a satisfactory outcome. But an apparently perfect operation may be followed by a breaking down of the clot. We have often been surprised to secure primary union in a case where it seemed folly to have expected it and, on the other hand, we have been equally surprised at the breaking down of a clot in a case where there appeared to be every reason to anticipate prompt and perfect union. There seems to be, in some cases, an element within the patient over which we have little or no control, and at present I know of no way to determine positively in advance of the operation which wounds will heal quickly and which will require more time. We do know, of course, that many of these patients are in very poor physical condition at the time of operation. They are extremely toxic, and even though they had been strong and healthy individuals prior to the local or systemic infection, they are then reduced to a point far below par; their illness shows, in itself, a lowered state of resistance and, what is of more importance in this connection, though far more difficult to recognize, they have not at the time any recuperative power, — any ability to make new tissue. I have been able to recognize a few of these cases when operating and to predict that though the operation would cure the mastoiditis and relieve the patient of discomfort and danger, the wound would not immediately heal. In such a case the patient is simply in a state of lethargy; the wound looks healthy, there is no pus, but the clotted blood melts away because the patient does not possess the tissue-building properties necessary for its organization. For a week or ten days such a patient makes but little advance and then, slowly, granulation begins. The attacking foe has been eliminated by the operation, the toxins have been thrown out of the system, and with the tonic effect of rest the patient once more commences to live actively. If, now, such a wound be properly cleansed and the margins freshened and sutured together, prompt healing will result, as described in the above quotation from Professor Mygind.

I first employed the method in this way on Feb. 5, 1906, exactly five years ago, on a patient whom we were anxious to send home from the hospital. She had been very ill at the time of the mastoid operation and the wound made but little progress towards healing. Even when she had begun to improve markedly in her general condition it was evident that a long time would be required to secure complete healing of the wound, and the impossibility of securing proper attention for her if allowed to return to her own home caused us to give serious consideration to the problem. Dr. M. B. Kelly, who was then resident physician at the Baltimore Eye, Ear and Throat Hospital, suggested that I treat the wound similarly to my method of dealing with cases of mastoid fistula, several of which had come to us from other institutions. Accepting the suggestion, the patient was anesthetized, the wound carefully cleansed, all granulation tissue curetted away until we had the bone cavity in much the same condition as it was at the close of the original mastoidectomy, the skin margins were freshened and sutured together, while the cavity filled with blood from the subcutaneous tissues. Nine days later the patient left the hospital with the wound completely healed; the temperature had never risen above normal, and there was practically no scar.

Since that time I have had a number of opportunities to repeat the experience and in only one instance (which had followed a serious case of scarlet fever) have I failed to get prompt healing. Of these operations I shall relate but one or two of the more striking examples to further illustrate the benefits and applicability of the method. In July, 1910, I was called to the Infectious Disease Hospital (Sydenham) to see one of the nurses from the Johns Hopkins Hospital who had been taken there because of scarlet fever. She developed mastoiditis and was operated upon July 2, while in the desquamative stage of the disease. The wound was closed, but primary union did not materialize. Three weeks later, when desquamation had ceased and the patient was progressing satisfactorily save for the fact that a mastoid dressing had to be submitted to every second day

and there seemed to be no means of determining how long this might have to continue, I explained to her the possibility of a speedy cure and secured permission to perform a secondary operation. The wound healed completely in five days and she was able to leave the hospital at the end of a week.

During the past year I have operated upon two patients with persistent open wounds, or fistulæ, after mastoid operations performed elsewhere. The first was operated upon twice by an able general surgeon, with whom I saw the patient in consultation and advised a third operation, suggesting that he cleanse the wound thoroughly and close the skin incision. The patient was sent to the hospital, but for some reason or other operation was postponed and about a month later the boy appeared in my clinic at another hospital. I cut out all the old scar tissue, cleaned out the mastoid cavity and closed the wound, using a deep tension suture near the center to lessen the strain upon the subcutaneous running suture, and secured prompt healing. The second case referred to had been operated upon three times in as many different cities and came to me with an unhealed mastoid wound. Removal of the scar tissue, complete exenteration of the mastoid cells and closure of the wound was followed by immediate healing with almost no visible scar.

I might describe other cases in detail, especially those in which primary union was not sought, but where the wounds were packed and a secondary closure performed after a delay of from one to three weeks had allowed the patient to recover better general health, but while possibly interesting, such details would add little to the value of this suggestion. The points I particularly wish to place before you are these:

1. Mastoid fistulæ do not ordinarily require elaborate plastic operations, with the formation and transposition of skin flaps, but may be closed by repeating what was or should have been done at the time of the original mastoid operation, and primary union will almost surely follow the closure of such wounds.

2. If you fear to attempt primary union after mastoidectomy, or if your attempts in that direction are attended by failure, this method of secondary closure offers you an *alternative* or a *corrective*. You may pack the wound at the time of operation in the ordinary way, and at some later date, when sure that the local infection has been controlled, if not eliminated, and that the patient is satisfactorily convalescing, you can recleanse and close the wound with every assurance of safety and speedy healing.

3. The advantages to be gained are: The saving of at least a month in the time required for healing; the saving of much discomfort for the patient and trouble for the surgeon; and the substitution of a small linear scar for a rather unsightly one with more or less depression.

## THE ALLEGED INCREASE OF NERVOUS DISEASES.*

BY PHILIP COMBS KNAPP, A.M., M.D.,

*Clinical Instructor in Diseases of the Nervous System, Harvard Medical School; Physician for Diseases of the Nervous System, Boston City Hospital.*

Some years ago, in an article in one of the popular magazines, I attempted to show that the popular belief in the "extraordinary prevalence of nervous disorders on this continent," and the rapid increase in those disorders due to the "heavy task imposed upon the nervous system in adjusting itself to a new environment and in meeting new demands," — to quote certain non-medical "authorities" on nervous diseases, — was not founded upon definite knowledge. At that time I based my arguments rather upon a consideration of the causes of nervous disease. There can be no question that there has been a diminution in the amount and severity of infectious diseases, or that toxic factors are less evident to-day. There is less abuse of alcohol; there is less danger from poisons used in manufactures, — lead paralysis, for example, is comparatively rare in our hospitals as compared with its frequency thirty years ago. Not only is the average duration of life longer, but the sanitary conditions and the health of the community is better. In one respect, however, there has been an increase in the frequency of certain etiological factors, — those due to violence, — as is shown by the increasing number of deaths from that cause. The psychical factors in the causation of nervous disorders, too, are probably less intense than in former times. Not only is the duration of life prolonged, but there is greater security for life and property. War may be hell, but it is certainly less hellish, even in Port Arthur, than it was less than a century before in Badajos. Speculation is nerve destroying to-day, but so it was in the days of the South Sea Bubble, when men gambled away thousands of pounds in a night. It is even possible that the sexual trauma, so dear to Freud, may have had an influence, if not upon Joseph in the Potiphar affair, at least upon his sister Dinah in her encounter with Shechem, the son of Hamor, in the outskirts of Shalem.

It does not necessarily follow, however, that, because the causes of nervous disease are less powerful to-day than they were in the past, there is an actual diminution in the amount of such disease. There ought to be such a diminution, but *a priori* arguments are sometimes fallacious. Data upon this point are scanty, except in regard to the one group of mental diseases. I am able to present a few statistics, covering precisely a generation, which have some interest. They are derived from the clinic for nervous diseases at the Boston City Hospital between the years 1877 and 1908 inclusive.

I am perfectly well aware that such figures are unsatisfactory. A certain number of cases of nervous disease are treated in other departments

* Remarks at a discussion on the increase of nervous and mental diseases at a meeting of the Boston Society of Psychiatry and Neurology, Nov. 17, 1910.

of the hospital; a considerable number of patients come to the neurological clinic who have no nervous disease at all, but who are obscure cases sent for diagnosis or cases for whom electrical treatment seems desirable; the out-patient clinic is a fluctuating mass, influenced by convenience of transportation, hard times, bad weather and the like; yet still those factors remain fairly constant from year to year, so that it is fair to assume that, although the total number of cases that come to the neurological department are not all nervous cases, any decided increase or decrease of the total number would probably mean an increase or decrease in the number of cases of actual nervous disease treated there.

Some of the factors which would influence attendance upon the clinic have been fairly constant. There has been no new clinic for nervous diseases of any importance established in the city in the last twenty-five years to take away patients from the City Hospital. There have been few changes in the staff, mostly in the subordinate positions. There have been but six physicians, two of whom served only two or three years; two others were connected with the department for about twenty years, and the two senior physicians for over twenty-five years.

On the other hand, certain factors would naturally have a tendency to increase the attendance. There are vastly improved facilities for treating the patients. Those familiar with the hospital twenty-five or thirty years ago may remember the nervous out-patient department — a small back-entry, which was a general thoroughfare, and an examining room not much larger, containing a large table covered with the apparatus of the throat department, a small stand containing the whole armamentarium of the neurological department for diagnosis and treatment, to wit, one small faradic battery which sometimes worked, and a rickety sofa. Assistants and externes were unknown. At present the department has nine good rooms, beside a special waiting-room and a laboratory, a complete equipment for galvanism, faradism, static electricity, high-frequency and thermo-electricity, a full supply of instruments for diagnosis, a department for massage, for the Fraenkel treatment and for defects of speech, and several assistants and externes in constant attendance. The population of the city has nearly doubled. In the last twenty-five years the great influx of Russian and Polish Jews into the city has occurred, and has been very noticeable in the clinic. It is an admitted fact that these new immigrants are a peculiarly neurotic race. All these things would naturally tend to increase the attendance at the hospital apart from any special increase in the total percentage of nervous disease in the community.

An increase has been noted, as the following table will show. This table has been derived from the annual reports of the hospital, but, instead of giving the figures for each year, I have taken the averages for five-year periods, beginning with the year 1879. The out-patient department of the hospital was established in 1865, but the department for nervous diseases not until 1877. The first two years, during which the department was started, are therefore omitted.

This table shows certain interesting facts. In the first place, we may note the enormous increase in the total number of out-patients coming to the hospital in the last decade, nearly twice as many as ten years ago, — an increase not warranted by any increase in the ill-health of the community, and perhaps not by any decrease in the wealth of the community. The number of nervous out-patients has increased, too, about commensurately with the increase in the population; but, if we glance at the column showing the percentage of nervous patients to the total number, we see not an increase, but a surprising decrease. In spite of the increase of Jewish patients and of the greater facilities for treatment, there are only half as many nervous patients to-day, as compared to the total number of out-patients, as there were twenty-five years ago.

| Periods. | Average of total number of out-patients per year. | Average of nervous out-patients per year. | Percentage of nervous patients to total number. | Population of Boston. |
|---|---|---|---|---|
| | | | | 1880. |
| 1879–1883 | 11,869 | 336 | 2.8+ | 362,839 |
| 1884–1888 | 11,903 | 435 | 3.7− | |
| 1889–1893 | 14,445 | 527 | 3.7− | |
| 1894–1898 | 20,365 | 592 | 2.9+ | |
| 1899–1903 | 29,827 | 669 | 2.2+ | 1910. |
| 1904–1908 | 39,350 | 689 | 1.8− | 670,585 |

These are the records of one hospital, during only a brief period, a single generation. Statistics are deceitful. As far as these go, however, they show no indication in this community of that "terrible increase in nervous diseases" so dear to the yellow journalists and the authors of works on psychotherapeutics.

## Clinical Department.

### AN INFECTION OF THE BLADDER WITH PENICILLIUM GLAUCUM.

BY ARTHUR L. CHUTE, M.D., BOSTON.

INFECTIONS of the bladder are due in an overwhelming majority of instances to one of the relatively common organisms; rarely, however, we see bladder infections that are due to yeasts, and occasionally cases of cystitis have been found in which the infection was with one of the moulds. The case I am to report belongs to this last group

and must be considered more as a rarity than as a condition having great clinical interest.

The patient, a woman of sixty-one, the mother of three children, came under my care in June, 1910. She had had trouble with her bladder as a girl, but her present trouble began about three years before with the symptoms of an acute cystitis. Two years before, because of her bladder pain, this woman was operated upon for a cystocele, rectocele and small carunele or prolapse of the urethral membrane. As she had relatively little relief following this operation, her condition was supposed to be largely neurasthenic and she was advised to go without local treatment and, in as far as possible, to disregard her trouble. This she did for a considerable period, but a short time before I saw her she had been forced to again take up treatment. She had been etherized, her urethra dilated and her bladder touched with nitrate of silver, on three different occasions, in the preceding four months. This treatment had given her a good deal of temporary relief and on one occasion she had remained comfortable for nearly five weeks, but after a time her discomfort referred to the bladder and her frequent and painful urination had returned.

It had been noted that her urine had contained for some time little white masses that floated on the surface. Previous to the last time she was etherized she had been given a dose of castor oil, and when her physician put an endoscope into the bladder he got several drops of fluid that had much the color of castor oil and which was slippery and oily. This last circumstance, combined with a considerable bowel looseness, had raised the question as to the possibility of an entero-vesical fistula.

On examination it was found that this patient did not completely empty her bladder. Her urine showed a trace of albumin, but no sugar; it contained many little white floating masses. They were quite different from the little granular masses of pus that one occasionally sees, in that they floated on the surface. Her bladder, which would hold 4 oz. of fluid, was diffusely red and had lost its normal markings. At its vertex there were some brilliant white masses, irregular in shape, that I believed at first sight were phosphatic incrustations on a new growth; there were also a few small white patches on the lateral bladder walls.

An investigation of the white masses in the urine showed that they were greasy when rubbed between the fingers; that they could not be satisfactorily stained with ordinary aqueous stains, but that they could be stained by heating carbol-fuchsin. The masses were made up mostly of amorphous material, but contained a certain number of round tufted bodies, in some of which little dark bodies could be seen; in others there were little vacuoles or spaces as though similar bodies had occupied these. There were collections of what looked like very large cocci, but which seemed too large for any of the ordinary cocci and also to vary more in size than is usual with cocci; they were thought to be masses of spores that had come from these spore cases. There were no definite bacteria that I could recognise, and relatively few pus cells. The white greasy masses were found to be soluble in ether and to burn on a loop with a snapping similar to that often seen with fatty substances. A second cystoscopic examination showed that the brilliant white masses at the top of the bladder could be moved about freely and by suprapubic pressure could be displaced into different positions; they were evidently masses of the white material that were floating on the surface of the distending medium. There was no new growth to be seen and no sign of any communication with the intestine.

It seemed evident that her trouble was a very stubborn infection with some yeast or mould; also, in the light of her history, it seemed improbable that palliative treatment would be successful in relieving the condition. Her bladder was, therefore, opened above the pubes. A considerable amount of the white material, and also some of the oily fluid, was skimmed off the surface of the distending fluid and preserved aseptically. The bladder surface was lightly rubbed with gauze and tube drainage established above while a retention catheter was put in the urethra.

The preserved material, left at room temperature, showed, in a few days, a considerable growth of an ordinary mould. It was given to Dr. Henry Perry for study, who found in the broken-up masses a certain number of mycelia; also some of the sporangia of the penicillium glaucum or common mould. Cultures made on various media showed nothing but penicillium glaucum. It was at first thought that this mould might be an air contamination, but the fact that Dr. Perry noted that the cultures made on agar and potato produced in growing a yellowish oily fluid, such as was found in the bladder, seemed to argue against the probability of air contamination. It seemed to point to the fact that this oily fluid was a product of the growth of the mould under certain conditions and that the white masses found in the bladder were due to a solidifying of this oily material when kept in contact with water. The fact that this white substance contained spores and was very light and floated, joined with the fact that this woman did not wholly empty her bladder, seemed to account for the difficulty in ridding her of the infection.

The surgical course of this patient was uneventful; the suprapubic opening was allowed to close at the end of four weeks. At the time she left the hospital this woman emptied her bladder completely, and examination failed to show any of the oily fluid or white masses that had been found so constantly before. She was also improved so far as her subjective symptoms were concerned. Her physician has since written me that she seemed well so far as the bladder process was concerned, though she had a ventral hernia at the upper end of the incision.

The only case that I know in the literature that bears much similiarity to this is the frequently cited case reported by Von Frisch.[1] His patient was also a woman in her sixties, who complained of symptoms of acute cystitis. She had a considerable residual and a marked hematuria. Von Frisch found in this woman's urine little white masses, the size of a hemp seed, a part of which floated and a part of which sank. He found that the floating particles had minute bubbles entangled in them that buoyed them up. When allowed to stand these bubbles disappeared and all the particles sank to the bottom. The little white bodies were made up of masses of mycelium. There were also yeasts and colon bacilli present. The gas in the urine was found to be carbonic acid gas and was due to the action of the yeasts on the sugar that this woman's urine was found to contain in amounts of from 2 to 4%.

The cystoscopic examination of this woman's bladder showed the same dazzling white masses that were seen in my patient. In Von Frisch's

[1] Soor der Harnblase: Wien. Klin. Wochenschr., 1898, vol. xi, p. 875.

case the mycelia and subjective symptoms disappeared in a few days under irrigations of nitrate of silver solution. There remained, however, the bacterial infection, which persisted for the four weeks the patient was under observation.

While Von Frisch's case and the one I have reported are somewhat similar, it will be seen that they are by no means identical. They both represent a type of bladder infection of which we have as yet relatively little accurate knowledge.

## Reports of Societies.

### NEW ENGLAND PEDIATRIC SOCIETY.

THE thirteenth meeting of the New England Pediatric Society was held Jan. 28, 1911, at the Boston Medical Library.

DR. JOHN LOVETT MORSE in the chair.

The following papers were read:

(1) PRESIDENT'S ADDRESS.[1]

JOHN LOVETT MORSE, A.M., M.D., Boston.

(2) WHEN SHALL WE REMOVE TONSILS AND WHAT TYPE OF OPERATION SHALL WE DO?[2]

EUGENE A. CROCKETT, M.D., Boston.

(3) WHAT IS TO BE THE ATTITUDE OF THE PEDIATRIST AND THE ORTHOPEDIST IN THE TREATMENT OF THE CHILD WITH CONGENITAL PTOSIS OF THE ABDOMINAL VISCERA?

JOEL E. GOLDTHWAIT, M.D., Boston.

(4) SILVER NITRATE IRRIGATIONS IN THE TREATMENT OF INFECTIOUS DIARRHEA IN INFANTS.

RICHARD M. SMITH, M.D., Boston.

DR. GREENE: I think Dr. Crockett's very interesting paper is worthy of commendation in many respects. There are a few points which it seems to me should be emphasized, and the chief one of them is the consideration of the shock and liability to hemorrhage from the operation of enucleation in adults as a reason why the radical method should be undertaken, in adults especially, with due deliberation and care. I feel perhaps a little more strongly than does Dr. Crockett about the importance of complete enucleation. The reason why the radical enucleation operation has come into vogue is that the results of partial operations in the past have been unsatisfactory, leading to a recurrence of the symptoms for which operation was done, and frequently making a second operation necessary.

If one examines a large series of cases in which partial operation has been done, and compares this with a series where complete operation has been done, the end results will be found to be strikingly in favor of the latter. The last word in the matter of technic of tonsil operations has not yet been said. The ideal type of operation in my opinion would be the most complete operation with the minimum of shock and hemorrhage.

DR. ROTCH: I wish to especially draw attention to the importance of operating upon enlarged tonsils and adenoids where they are evidently a cause of delayed development, especially of the thorax, but also when affecting the general condition of the child.

DR. LANE: I remember that once when the director of hygiene in the schools of a neighboring large municipality came out to Milton to speak before a society which was interested in the welfare of the schools there, he asked me if there was anything I would like particularly to have him speak about, and I suggested adenoids and tonsils. In the society were parents who had gone to their physicians for advice regarding the removal of tonsils and presumably adenoids in their children, and I am sorry to say that the director brought up the subject only to speak of the influence which fresh air and sunlight had upon the growths and tonsils and as opposed to operation, which to my mind was distinctly detrimental to the health of the children.

The specialist has to rely somewhat for the previous history upon the general practitioner who has seen the child with repeated attacks of tonsillitis, although at the present time the tonsils may be normal and there are apparently no indications for removal.

DR. GOLDTHWAIT: It has been my good fortune to see a good many tonsils removed in cases with rheumatoid joint conditions, and one thing which has impressed me is that if the tonsils are to be removed with the idea of removing the source of infection, they should be very carefully enucleated. I have seen several cases in which the tonsils were supposed to have been removed where there was enough of the substance remaining to make subsequent operation necessary. In cases in which the patients have not had much quinsy and much local signs of inflammation, accumulations of pus have been found which have been a very striking and a very distinctive feature in the joint conditions. It seems to me, and it has come to be my advice in speaking to patients about these conditions, that if the operation is to be performed for the removal of the tonsils to eradicate a means of infection, it should be a complete enucleation.

DR. MORSE: There are just one or two words that I want to say on the subject. I do not believe that the tonsils are the root of all evil, but do think that a good many things come from the tonsil, and to those which have been mentioned I would add nephritis as a sequela of tonsillitis. In young children, enlarged tonsils often interfere so much with deglutition that they take their food very poorly and have their nutrition very much disturbed on this account. There is one question which is often asked me which I wish Dr. Crockett would answer: If a young child's tonsils are removed, will it interfere with the development of a proper singing voice in after years?

DR. EASTMAN: I have seen two cases in the past year where the tonsils were removed, in both instances the removal effected with the tonsillotome, and several months later, as a result of this method, there was an infection resulting in glands in the neck. I cannot see any objection for complete removal of the tonsils even in a child.

DR. CROCKETT: I think that in reading a short paper on a long subject one's position is likely to be misunderstood. There are many cases which present no history pointing to the tonsils. The class of cases which present a rheumatic history, a history of tubercular glands, history of repeated obstruction, diseases of malnutrition caused by insufficient breathing space, — those are indications for removal, — those cases all need enucleation. In very many cases removal of the adenoids is sufficient. If I saw a case with large adenoids and small tonsils I would prefer to remove the adenoids and do my enucleation at a second operation if necessary, but in cases which present a clear history of infection from the tonsils, remove all that there is and do not leave any at all. Enucleation is a big operation and should not be attempted in a suburban town away from one who is competent to do it.

[1] See JOURNAL, p. 414.
[2] See JOURNAL, p. 414.

If the general practitioner wishes to do an enucleation, then let him get his patient near to the specialist, make all the necessary preparations and be prepared to meet the hemorrhage if it occurs. This is what one must always be prepared for. You can see it right down at the Eye and Ear Infirmary every day. I have been connected with the Infirmary for twenty-one years, and I suppose we do 600 or 700 operations a year; up to the year 1906–1907 I do not remember a single case of hemorrhage. Now I never finish a three months' service without seven or eight hemorrhages, and they are bad hemorrhages; they are fully as bad as an obstetrical hemorrhage, and if you do not go down and do something pretty quick, you will find a funeral when you get there. Now this is the point which I particularly wish to make. It is a form of operation which should not be entered into lightly, and one which should not be done twenty-five miles out of town; it is a hospital operation, and a serious one, and if it is done with care by the proper man it is all right. I do not mean to say that the specialist is the only one who can do the operation, but I do not think that the medical man is the man fitted to do it; it is a critical operation and it is not applicable in all cases of tonsil hypertrophy.

As to the effect on defective speech after removing the tonsils, it has been my experience that in cases of stammering, the condition is a mental one. It is a habit and is better treated by the nerve department, and I should think that operation would absolutely fail to improve it. The thick speech which tonsils and adenoids produces would be helped by removing the adenoids. Dr. Jelly has brought me quite a number of children from his class of backward children in the public schools, and in all cases, almost without exception, the difficulty was a nervous or mental thing and not at all referable to the condition of their throats, and another thing to be considered is that children imitate very readily.

I think that removal of the tonsils even in the singer's voice will probably improve the voice, but it will disturb their method, which is an important matter if the voice has already got its training, but the removal of tonsils in young children will improve the conditions and not do any harm at all. In rheumatism with an endocarditis I would not hesitate at all to do an enucleation. I would not remove the tonsils in the acute attack, that is, in the height of the rheumatic process with temperature and acute infection. I have seen it done a number of times, but my own feeling is that it always increases the septic process and the child is longer sick than usual. In the same way, in a patient with glands in the neck, I would rather delay the operation until after the acute process is over.

Dr. Joel E. Goldthwait, Boston, presented the following paper:

WHAT IS TO BE THE ATTITUDE OF THE PEDIATRIST AND THE ORTHOPEDIST IN THE TREATMENT OF THE CHILD WITH CONGENITAL PTOSIS OF THE ABDOMINAL VISCERA?

He said that anatomists have shown that one out of every five persons has a long mesentery to the transverse colon which allows a congenital ptosis of the same. This caused the person to take characteristic positions and resulted in impaired nutrition. A series of Roentgen-ray plates were shown which illustrated this condition. He then told how mechanical support could overcome ptosis.

Dr. Talbot: The plates which Dr. Goldthwait has shown us are very interesting and instructive. I have seen one or two such children and I have an x-ray plate similar to the ones just shown of a boy whose only complaint has been constipation. This boy had a ptosis of the transverse colon with a kink about half way up the descending colon. The ascending colon must have had a long mesentery because it was doubled up. A series of purgatives were tried without improvement. He was then put to bed with the same result. His stools were examined for the different food components (meat, starch and fat) and it was found that his digestion was normal. He was, therefore, given his caloric needs in foods which left the smallest fecal residue, that is, meats, sugars, fats and eggs. His abdomen came down about six inches in about two weeks. The whole clinical picture was a boy who was uncomfortable when he came in, having persistent constipation, and on going out he was a comfortable youngster who did not look particularly abnormal. Unfortunately, we did not get an x-ray to see what happened after he got a smaller food residue than previously. I think that treatment from the point of view of diet is equally important as the mechanical treatment.

Dr. Craigin: The point in diet which Dr. Talbot brought out interests me. Some of the men who have been treating these cases advocate the use of bulky foods to clear out the large intestine. I recall many young children of this anatomical type who had been fed largely on crackers, bread, potato and cereals. They improved immensely on cutting down the bulky foods and giving eggs, meat, fat and sugar.

I would like the opinion of others on the use of bulky foods. Is it not liable to aggravate the faulty mechanical condition?

Dr. Greene: I would like to ask if this type of ptosis can be present without causing any symptoms in the child, or whether this form always causes symptoms; can the child be a perfectly healthy one and yet have the condition?

Dr. Richard M. Smith read a paper entitled,

SILVER NITRATE IRRIGATIONS IN THE TREATMENT OF INFECTIOUS DIARRHEA IN INFANTS.[1]

He said that a solution of 3% silver nitrate had been used at the Boston Floating Hospital last summer in treating both the acute and chronic cases of infectious diarrhea. One pint of the solution was injected after the colon had been cleansed with a sterile water irrigation. In some of the cases an early injection apparently hastens the disappearance of blood from the stools and shortens the course of the disease. In some later cases where blood and pus persist in the movements, the ulcers can be stimulated to healing by the silver nitrate injections. Since no harm has followed the use of silver nitrate injections, and benefit has been received, it would seem worth while to give this means of treatment a further trial.

Dr. Rotch: This work, which has been done at the Floating Hospital, as reported by Dr. Smith, is extremely good and should induce physicians to make trial of it during the coming summer. It will probably be especially valuable in the more chronic forms of cases where actual lesions are present. This special means of treating cases of infectious diarrhea will, I hope, prove to be a most effective part of the general specific treatment which has lately been evolved in the bacteriological study of these cases. By what is called infectious diarrhea we understand a condition which is produced by organisms which penetrate the tissues. In this class of diarrheas, therefore, we have to deal not only with disturbances which are produced

[1] See Journal, March 2, 1911, p. 298.

within the intestine, but also outside of the intestine in the tissues. We also have to deal with local irritation of the bacilli within the intestine and a production of toxins; also with the effects produced by the absorption of these toxins and the destruction of proteid material in the tissues, thus interfering with normal metabolism. It seems probable that the character of the infecting organisms in respect to their work upon the proteids in the intestine may be changed by the giving of carbohydrate food and in this way lessening the production of toxins. For this purpose lactose can be given by the mouth, following the local treatment with laxatives and irrigations. It has also been proposed to give infusions of dextrose in order to restore to the blood the sugar which has been used up by the body during the starvation treatment as the most available form of energy. Considering how meager and inadequate our treatment of these cases has been in the past, I think that it is encouraging to at least feel that we in the near future may have three forms of specific treatment — by the mouth, by the rectum, and by infusion of dextrose.

DR. BOWDITCH: I am very glad to hear what Dr. Smith has to say about this treatment and think this procedure an excellent one. There is one thing I would like to have him tell us, and that is whether any post-mortem examinations were held on these patients which allowed him to see how far the silver nitrate penetrated. Another question is, what was the amount of the irrigation that he used. My own feeling is that the chronic cases are the ones which are more greatly relieved. I have seen one or two cases in which after ten days' duration, with a certain amount of prolapse, one injection of silver nitrate of about eight ounces was sufficient to stop all subsequent mucousy, bloody movements and make them perfectly normal. If we can help a child in that way it means a good deal to the further rapid convalescence of the case.

DR. PRAINO: I would like to ask if Dr. Smith has ever used argyrol in this connection? I have tried a 5% solution in a few cases and the results obtained were almost miraculous.

DR. JORDAN: I was very glad indeed to listen to Dr. Smith's paper, as this subject is of interest to me. I have seen a good many of these diarrheas in the last two years, and the use of silver nitrate solution in the bowels is something that I would not myself have tried without first hearing the reports that I hear to-night. Dr. Bowditch just spoke of something which I wish to touch on also. We do not know just how far the silver nitrate is going to penetrate or what harm it is going to do. To illustrate this point I will cite the case of a man who was coming to my office for treatment of a finger, and as it was not healing quite fast enough I tried the 5% silver nitrate solution to stimulate fresh growth, telling him to return the next day. He did so and I was surprised to find that the previously healthy granulations had all broken down and I had a very large ulcer there, so I wonder if the nitrate of silver may not do the same thing to the colon. I have two cases in mind which came to St. Joseph's Hospital on my service there last summer, a boy and girl from the same family. The boy was *in extremis* when he came into the hospital. He was having anywhere from thirty to forty stools, all of them foul with blood, mucus and pus, and Dr. Dwinell took a smear on a sterile towel with the intention of making an autogenous vaccine, and the smear showed so many different forms of bacteria that he was the greater part of a week trying to isolate anything which we felt safe in using, and by that time the boy began to improve. The treatment in this case was colon irrigations and an ounce of castor oil every three hours, kept up for four or five days, and elimination of the food with the exception of water and buttermilk. The sister was not as badly affected and she improved much more rapidly than the boy; but what I wanted to speak about particularly was the action of the nitrate of silver on these ulcers in the colon, and where we know so little about it, these reports would give encouragement, and I am very glad to know that the results were so good.

DR. LANE: I would like to speak of the use of the silver nitrate solution in two cases of infectious diarrhea, which we formerly called "dysentery," characterized by tenesmus and mucus, pus and blood in the stools, that occurred in my practice last spring shortly after Dr. Hewes' report of his results with a 5% solution. In these two cases in which I used it early, before the fourth day of the disease, the bacteriological examination later disclosed the proteus bacillus as the infecting organism. One child, three years old, had twenty-one stools in one day, after which I tried the 5% solution of silver nitrate, 8 oz., injecting it high after cleansing with warm water. There was no evidence of pain, but she did not retain even the 8 oz., as a part, perhaps 2 oz., was immediately expelled. Afterwards the characteristic appearance of the stools was such as Dr. Smith has described, with the exception that the number was increased, there were twenty-four in the next twenty-four hours, the odor was foul and the tenesmus was more severe. As there was no improvement after forty-eight hours, and I did not feel that one application was a fair trial, I repeated the irrigation, with the same results. The other case showed a similar lack of improvement under the silver nitrate irrigations and I was satisfied that the treatment did no good. I should hesitate to use it again.

DR. MORSE: I have not used this silver nitrate irrigation in any of the acute cases of diarrhea, but have in a small number of chronic ones, and my feeling is that most of them have been helped to a greater or less extent, some of them a good deal. I certainly have been so favorably enough impressed with the results that I feel that next summer this is one of the things I shall try more regularly than in the past.

DR. SMITH, closing the discussion: As to the question of post-morten findings, in the cases to which I referred which proved fatal, we were unable to get autopsies, so I do not know how far up the colon the silver nitrate penetrated. I am sure that none of the patients on the Floating Hospital were in any way harmed by the treatment. None of them seemed to be worse after its use. The cases which Dr. Lane has referred to are of value in a discussion of this sort. It is one of the points I tried to bring out, that since no harm is done by this treatment, it is perfectly fair to try it in a greater number of cases of summer diarrhea, for we stand a reasonable chance of quickly relieving the condition. I have not tried argyrol in any of the cases. I have seen a favorable report of its use by some one else. Dr. Bowditch asked about the amount of the irrigating fluid. In all cases we used a pint of silver nitrate solution following a preliminary cleansing irrigation.

## Book Reviews.

*Refraction and Motility of the Eye. For Students and Practitioners.* By ELLICE M. ALGER, M.D., Adjunct Professor of Ophthalmology at the New York Post-Graduate Medical School. Philadelphia: F. A. Davis Company.

There seems to be no crying need for more books on testing the eyes for glasses, but if books

appeared only when there was a crying need for them, our paper mills would not be as busy as they are. This book of 380 pages is clearly written and well printed and bound. Naturally the author has little original, but the work is an efficient guide for the testing for glasses, and the second half of the book, on the motility of the eye and its anomalies, is sufficiently complete and accurate. Chapters on color blindness and the field of vision are added.

*The Principles of Hygiene. A Practical Manual for Students, Physicians and Health Officers.* By D. H. Bergey, A.M., M.D., Assistant Professor of Bacteriology, University of Pennsylvania. Third edition. Illustrated. Pp. 555. Philadelphia and London: W. B. Saunders Company. 1909.

The title is a misnomer. The volume consists too largely of detailed quotations from various sources, the author failing to make clear the principles upon which the study of hygiene is based. In a textbook where principles are essential, this is unfortunate. Moreover, the author's choice of some authorities to the exclusion of others impairs the value of the work to the student or the health officer who wants to be well informed. The medical student may not care to read fifty dairy rules prescribed by a single authority; to be told, among other things, that "cows should not be moved faster than a comfortable walk while on the way to place of milking or feeding," but he does want to know what constitutes an unobjectionable dairy, with the reasons therefor, so that he himself may be in a position to make such rules as in his judgment may be necessary.

Rules governing barbers issued by the New York City authorities, or regulations for the control and management of piggeries in the state of Pennsylvania, belong in the appendix, if in any portion of a book on principles of hygiene, and the same may be said of the forty pages devoted to the quarantine laws and regulations of the United States.

The student interested in the study of industrial hygiene will be surprised to find, in a chapter almost entirely made up of abstracts and of extracts from writers, no reference whatever to one of the most important works on the subject in the English language.

The chapter on water and water supply is rather carelessly written and appears to be the work of a person who knows little more about the subject matter than he has gained from reading books similar to his own. Many statements do not appear well considered. In a discussion of "contamination of drinking water by poisonous metals," little knowledge of the subject of lead poisoning is shown by the statement that "since the solvent action upon lead is a rather slow process, there is very little danger from the plumbing of modern dwellings, unless water is used that has been standing in the pipes for some time." On page 111 the writer quotes De Chaumont's classification of waters as regards their degree of purity, but, except for a brief statement that "it is always necessary to have some knowledge of the geologic formation of the locality," the table is very misleading. For example, any one in New England following the figures given might be led far astray. The waters of Massachusetts containing from 14 to 40 parts per million of chlorine would certainly be placed in the "suspicious" rather than in the "pure" or "usable" class; and other like criticisms of the table could be made. On page 113 is the statement that "if the population on the watershed exceeds about 100 per square kilometer the stored water is in danger of being polluted and often proves troublesome from bad taste and odor." While it is true that the stored water might be in danger of pollution from this population, troublesome conditions from bad taste and odor are seldom if ever due to the population upon a watershed so sparsely settled as to be considered a suitable gathering ground for a water supply. The division of ground water supplies into two classes, page 115, is hardly accurate. On the whole, the discussion of water purification is more satisfactory than the statements previously made in the same chapter on matters relating to water and water supply. The author, however, appears not to be sufficiently familiar with the literature on the subject to give due prominence to its important features, whereas he frequently allows minor points to occupy too large a portion of the chapter. Similar criticism might be made concerning the chapter on "Removal, Disposal and Purification of Sewage." If, for example, one were to depend alone upon this chapter for information on the subject, one would get a distinctly erroneous opinion of the relative importance or use of different methods of sewage purification.

The volume falls far short of meeting the needs of students and physicians and consequently compares unfavorably with the leading textbooks on the subject.

*A Manual of Toxicology.* By Albert H. Brundage, A.M., M.D., Pharm. D., M.S., Professor of Toxicology and Physiology in Marquette University in the Departments of Medicine, Dentistry and Pharmacy; formerly President of the Board of Pharmacy of the State of New York, etc. Seventh edition, revised and profusely illustrated. Brooklyn, N. Y.: The Henry Harrison Company. 1910.

As the name implies, this work is only a manual, giving a concise presentation of the principal facts relating to poisons. There are detailed directions for the treatment of poisoning, and a table of doses of some of the principal and many of the new remedies. The colored plates constitute a valuable part of this work. The book can be considered an excellent one for teaching purposes, but of less value to the practitioner of medicine, who usually wants all of the information available when he encounters a case

of acute poisoning. A book, however, cannot pass through six editions without having merit, and we can heartily recommend it.

*Vaginal Celiotomy.* By S. WYLLIS BANDLER, M.D., Fellow of the American Association of Obstetricians and Gynecologists; Adjunct Professor of Diseases of Women, New York Post-Graduate Medical School and Hospital; Associate Attending Gynecologist to the Beth Israel Hospital, New York City. With 148 original illustrations. Philadelphia and London: W. B. Saunders Company. 1911.

This is a handsome monograph of 450 pages with 148 full-page plates, all printed on heavy glazed paper and dedicated to A. Dührssen. The book treats of all the operations usually performed on the uterus, tubes and ovaries by way of the vagina by means of descriptive text and very good original drawings from actual operations. The topics considered are: Posterior Vaginal Celiotomy; Anterior Vaginal Celiotomy; Simple Vaginal Hysterectomy; Diseases of the Adnexa; Hysterectomy; Myomectomy; Hysteromyomectomy; Vaginal Cæsarean Section.

The illustrations are well drawn and reproduced, so that the different steps of the author's technic are made most plain, and the full legends under the figures assist the reader materially in following every successive move of the operator.

The book is to be warmly recommended to those operators who operate on the uterus and its appendages by the vaginal route.

*Andreas Vesalius, The Reformer of Anatomy.* By JAMES MOORES BALL, M.D. St. Louis: Medical Science Press. 1910.

This monograph of one hundred and forty-nine pages including a detailed index is an admirable account of the life and work of Vesalius, a man known unfortunately chiefly by name rather than by personal acquaintance with his contributions to anatomy. This is perhaps natural since his writings were in Latin and were published prior to the middle of the sixteenth century. Dr. Ball's work can, therefore, not be too highly commended since it brings before modern readers in most attractive form historical knowledge otherwise difficult of attainment. The monograph is beautifully printed and profusely illustrated from old cuts. It should find a place not only in medical libraries, but also in the private collections of individual physicians. The public spirit which prompts the preparation and publication of such books should certainly be acknowledged by their purchase.

*Golden Rules of Diagnosis and Treatment of Diseases.* By HENRY A. CABLES, B.S., M.D. St. Louis: C. V. Mosby Company. 1911.

This volume in the Medical Guide and Monograph Series bears the sub-title, "Aphorisms, Observations and Precepts on the Method of Examination and Diagnosis of Diseases, with Practical Rules for Proper Remedial Procedure." It consists of a series of Polonius-like pellets of chemical wisdom, — derived partly from the literature, partly from the author's personal experience, — combined with selected prescriptions and therapeutic measures into a sort of anthology of diagnosis and treatment. Its persistent iteration of "*Remember*," in black-faced type, seems to carry a connotation of "*Memento mori*." Doubtless it will serve as a useful *vade mecum* to the class of physicians who practice medicine by rule of thumb.

*Inebriety.* By T. D. CROTHERS, M.D. Cincinnati, Ohio: Harvey Publishing Company. 1911.

This volume, as its sub-title states, is "a clinical treatise on the etiology, symptomatology, neurosis, psychosis and treatment and the medico-legal relations" of alcoholic inebriety. It is based on the modern conception of alcoholism as a disease. From a practical point of view this is doubtless sound, though it may technically be questioned whether the condition should not rather be regarded as a symptom-complex, a manifestation of a more fundamental morbid process. In the chapter on "Peculiarities of Conduct and Thought Traceable to Inebriety," the author refers to the delusions induced by alcohol, and in so doing touches what seems the real essence of the problem. For however much good medical treatment of inebriety may do for individuals, alcoholism as a disease of the community can never be eradicated until by education the human mind is brought to recognize the use of alcohol as one of the fallacies of life, a baneful custom of society inherited as a legacy from preceding generations and accepted without criticism, as other fallacies are accepted and so persist, the incubus of the ages.

*Hints for the General Practitioner in Rhinology and Larynology.* By DR. JOHANN FEIN, Privatdocent at the University of Vienna. Translated by J. BOWRING HORGAN, M.B., B.Ch., late Surgeon at the Hospital for Diseases of the Throat, Golden Square, London, W. New York: Rebman Company. 1910.

This small book of two hundred pages is intended to give the general practitioner as much as he could reasonably be expected to know about diseases of the nose and throat. It is entirely practical, and contains several useful hints. As examples may be cited the fact that nose bleed practically always comes from the anterior part of the septum and can be easily controlled, that a unilateral purulent nasal discharge in children often means a foreign body, that throats often appear to be inflamed or swollen when there is nothing important the matter with them, that in cases of cough with expectoration the secretion always come from below the larynx. Exception might be taken to some of his statements, and he has rather a tendency to unnecessary treatment, but as a whole the book answers its purpose well.

THE BOSTON
# Medical and Surgical Journal.

THURSDAY, MARCH 23, 1911

*A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.*

*All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.*

*Remittance should be made by money order, draft or registered letter payable to*

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

## DR. JOHNSON AND THE MEDICAL PROFESSION.

IN the March number of the *Practitioner* is an entertaining article, by Dr. Wynne, under the above title, describing some of the relations between the great lexicographer and the medical men of his time. Johnson, by reason of his physical ailments, was a man who "suffered many things of many physicians," and in his time was attended by Dr. Pott, who gave his name to spinal caries and to his own fracture; by Dr. Heberden, he of the "nodes"; by Drs. Brocklesby and Warren, and by Messrs. Cruikshank and Levet, of lesser fame. But, like all good patients, Johnson loved his doctors and seems to have been sincerely grateful for their ministrations, which in those days of blood-letting and purgation cannot always have been pleasant. He entertained evidently a high and unshaken opinion of the profession, for in his sketch of Dr. Samuel Garth, in "The Lives of the Most Eminent English Poets," he says: "Whether . . . it be true that physicians have had more learning than the other faculties, I will not stay to inquire, but I believe every man has found in physicians great liberality and dignity of sentiment, very prompt effusion of beneficence, and willingness to exert a lucrative art where there is no hope of lucre." This tribute, like many of Johnson's grandiloquent dicta, goes straight to the point with almost epigrammatic incisiveness and is the more gratifyingly complimentary that it attributes to the doctors of that age qualities which we are still proud to be thought to possess.

Dr. Johnson's associations with physicians were not solely professional. Two of them, Dr. George Fordyce and Dr. Warren, were members of his celebrated "Literary Club"; and three, Drs. Heberden, Brocklesby and Horsley, the latter perhaps a progenitor of Sir Victor, belonged to another club that Johnson later founded at the Essex Head Inn. The fact that doctors of medicine were welcomed in such social and literary organizations, as Garth had been to the Kit-Kat Club, is another compliment to the profession, which in this respect also does not seem to have changed its characteristics with time. It has recently been said by a gentleman in Boston, not a physician, that the doctors manage every club they get into, and do it better than any one else, a statement that contains an acknowledgment of efficiency even though originally spoken with a suggestion of criticism. The doctors of Johnson's time probably did not manage clubs as they are now accused of doing, but doubtless their sociable temperaments were much the same then as now. Johnson apparently enjoyed their society, for Boswell says of him that he "had in general a peculiar pleasure in the company of physicians."

Dr. Johnson, though a radical thinker, was commendably orthodox in his medical opinions. He hated quacks as he hated all shams, and his denunciations of several charlatans of the time were merciless. One could wish that he might have written on some of the popular delusions of our own day. He was not an inveterate conservative either, but liberally alive to rational progress. "Inoculation" [against smallpox], he said, "has saved more lives than war destroys. And the cures performed by the Peruvian bark are innumerable." He would have been a good champion to oppose the anti-vaccinationists. Though doubtless often indiscreet in his diet, and neglectful of bodily exercise, for which he suffered, he seems to have entertained sound ideas on many hygienic matters. Like Benjamin Franklin, he believed in the benefits of fresh air, for, says Boswell, "he sets open a window in the coldest day or night."

These and many other points of interest, which are noted in Dr. Wynne's article, are pleasant reminders of the cordial relations between Dr. Johnson and our profession, which in many instances has enjoyed such agreeable association with that of literature.

## RECOMMENDATIONS FOR THE PREVENTION OF DEGENERACY.

LAST spring the Massachusetts State Legislature passed a resolve providing for the appointment, by the Governor, of a commission of five

to "investigate the question of the increase of criminals, mental defectives, epileptics, degenerates and allied classes." This commission, of which Dr. Walter E. Fernald was chairman, pursued its investigations during the summer and autumn, and under date of Jan. 14 rendered a report which has recently been made public and which contains some interesting statistics, conclusions and recommendations.

The commission divided the subject material of its study of degeneracy and disease into four groups, — crime and criminals; the insane; the feeble-minded and epileptic; and paupers, — and collected data of increase or decrease in each of these groups during the past twenty years by five-year periods. These statistics are carefully tabulated and compared, and from them the following conclusions seem to the commission justifiable: First, that although there has been a decrease in the ratio of the total number of crimes to the population, there has been an increase in the group of crimes against public order and in the more serious crimes, such as assault, robbery, manslaughter and murder, the latter chiefly among recently admitted alien immigrants; second, that although there has been a large increase in the ratio of insane patients in hospitals to the population, only one fifth of this is due to increase in the ratio of admission of new cases of insanity, and there is no evidence of a marked increase in the number of new cases in the community; third, that there has been a large increase in the number and ratio of feeble-minded and epileptic persons under treatment in institutions, but that the facts obtainable do not prove that there has been an actual increase in the ratio of such persons to the population; fourth, that from all the information obtainable there is evidence that there has been a decrease rather than an increase in pauperism.

These conclusions, as drawn by men of reliable judgment, certainly seem encouraging, but they should encourage the community to adopt measures towards further improvement rather than to rest satisfied with the present status. The criminals, insane, feeble-minded and epileptics may fairly be taken as representing the class of unfit whose increase in the community is undesirable. The commission was impressed with the fact that these types of degeneracy are often strikingly grouped in families and seem to represent "different phases or expressions of the same fundamental defect." To prevent the birth of such defectives and degenerates, it, therefore, recommends "extending the policy of custodial care of the feeble-minded, epileptic and insane, especially of women of the childbearing age, and prohibiting the marriage of mental defectives, confirmed drunkards and habitual criminals, as that of idiots and the insane is now forbidden." It acknowledges that such measures would not be complete, but believes they would do good and would not provoke public opposition. It does not recommend the surgical sterilization of male defectives, criminals and drunkards by vasectomy, since it believes that this procedure would tend to increase sexual vice and the spread of venereal disease and has not yet been proved an efficient substitute for permanent segregation and control. The commission regards the abuse of alcohol and the prevalence of syphilis as the two chief factors in the production and perpetuation of degeneracy. For the former evil it can offer no remedy other than the slow education of public opinion; for the latter it advocates the systematic teaching of sex hygiene to the young, and special provision for the treatment of syphilis in general hospitals. It advocates also further restriction of immigration and makes many minor recommendations.

Altogether, the report of this commission is an exceedingly instructive document and affords much valuable suggestion for thought and for action. Its most encouraging aspect is as an evidence of a disposition on the part of the community to look inherent evils squarely in the face and to endeavor to remove them by the gradual adoption of rational preventive measures.

## SMALLPOX AND VACCINATION IN THE PHILIPPINES.

AN article by Dr. Robert Olesen, in the issue of the *Medical Record* for March 4, describes the author's studies on "Smallpox and Vaccination in the Philippine Islands." Essentially the same data are presented in a paper by Dr. Victor G. Heiser and Dr. Olesen in the Public Health Report for March 10 of the United States Public Health and Marine-Hospital Service.

During the Spanish hegemony in the Philippines smallpox was extensively prevalent because no particular effort was made to control it except by segregation of actual cases, and there was no attempt at protection of the natives by vaccination. In the six provinces near Manila, with an approximate population of 1,000,000, there had been under Spanish rule an average annual mortality from smallpox of at least 6,000. Following the American occupation of the islands

in 1898, systematic universal vaccination of the inhabitants was begun, and since that time there have been performed there approximately 9,000,000 vaccinations and revaccinations. The incidence and mortality of smallpox immediately and steadily declined. Since 1907 there have been but a few scattering cases in the six provinces near Manila noted above, and not a single person who had been successfully vaccinated has died of smallpox. Similar gratifying results have been obtained on other islands in the archipelago.

Naturally the greatest resistance to this prophylactic compaign had been experienced from the ignorant aborigines, and the credit of its brilliant achievement in the face of discouragement and almost insuperable obstacles belongs to the personnel of the Public Health and Marine-Hospital Service. The problem of the complete eradication of the disease from the islands is that of continuing the present policy. The birth-rate among the natives is high, and each year there are many new persons to be vaccinated and revaccinated. The labor and expense are great, but they are justified by the results.

The papers by Dr. Heiser and Dr. Olesen deserve reading in full. They constitute a cogent argument against anti-vaccinationists, by demonstrating a most impressive modern instance of the benefits of prophylactic inoculation against smallpox, the record of which establishes one of the great services to mankind by the medical profession.

## DOCTORS AND BARBERS.

A DOCTOR can hardly pay his periodic visit to the barber, as in company with the rest of mankind he is bound to do, without being stimulated to reflection on the origin of his own profession. The barber is the prototype of the surgeon. It was he who, in the courts of kings and emperors, first began that mechanical ministry to the personal physical well-being of man which constitutes the business of the profession. Doubtless at first he learned by dressing the accidental wounds which he himself produced, and later his growing proficiency with razor and shears gave the suggestion to other surgical procedures. Of all handicraftsmen he was most delicate and adept and most accustomed to gentle contact with the person; hence it was naturally he who was called on to set the broken bone and stanch the flow of blood from a wound. The oils and spices which he used were tentatively applied to sores and septic sinuses, and, being generally bland and sterile, acquired a reputation for curative virtue.

Probably few professions have so gained in distinction as that of surgery. Its progress in this respect is something like that of the dog, always an object of the basest contumely in Homer, but now risen in caste until recognized as one of the noblest friends of man. The barber-surgeon in early days was unceremoniously booted about camp or court, and admitted to the company of his betters only when he was desired to discharge his mystery. Gradually his growing knowledge enabled him to command more respect, but even in the Middle Ages he was only an upper servant. By this time, however, the surgeon divorced himself from the barber and evolved into a separate entity, much as man and the apes may be conceived to have diverged from a common simian ancestor combining the potential characteristics of each.

Anesthesia and bacteriology in our own time have completed the emancipation of the surgeon and placed him on a pedestal of eminence at least equal to that of his medical brother of more distinguished but no less honorable lineage. Medicine may have descended from heaven as a gift of the gods, but surgery has arisen on earth out of the necessity of man and through the humble hands of the barber, its earliest prophet.

Meanwhile to-day the barber persists in his needful office and ministers to us, his distinguished kin, with a courtesy as free from envy as if he were not our poor relation. He retains, too, a skill closely cognate with that of the surgeon. 'Tis always a pleasure to watch a dexterous barber at his work, to observe in the mirror his ingenious shingling of the hair over his comb and feel the delicacy of his critical touch. Under his soporific manipulations one is inclined to assume towards him a very benevolently patronizing attitude, very different, for instance, from that which one feels towards the dentist as he pursues those diabolical maneuvers which are really so much more essential to our health and well-being. It is a painful fact of human experience that the things which are best for us are often most disagreeable or unattractive, whereas the things we really enjoy are generally unhealthy, expensive or immoral. The barber, however, is none of these, and we may relish the somnolent content of his ministrations without compensation.

Even this latter statement, however, must be immediately modified. For though one may once have submitted to the barber in security, the progress of medical science has spoiled all that. As a disseminator of infection the barber has

opportunities equalled only by those of the waiter, the cook and the manicurist. Unfortunately the general public fears chiefly only those infections which are trivial. But though for us scabies and tinea and pediculi may have lost their terror, the *treponema pallidum* still remains an object of apprehension in spite of salvarsan. The imaginative professional eye can see spirochetes crawling on the edge of the apparently innocent razor, and the distant prospect of tabes and paralytic dementia, to say nothing of more immediate evils, makes it impossible for any cautious doctor to allow himself ever to be shaved by a barber.

Our visit to the barber, however, may be productive of much varied and pleasurable speculation. He still remains akin to us, though separated by so many centuries of evolutionary progress. And though, under certain circumstances, we may "fear his skinny hand," in general his services are harmless and so refreshing that often we are glad to add to his fee a gratuity, as largess after the fashion of the potentates who were our earliest common patrons.

## AN OBSTETRIC ANOMALY.

In the March number of the *Edinburgh Medical Journal* is an interesting abstract of the comments by Dr. F. Mirto "upon certain phenomena in the labor by which one of two pygopagous twins gave birth to a child." A pygopagus is defined as "a double monster with union at the buttocks." These twin sisters in question, Rosa and Giuseppa Blazek, were united back to back "by the sacral and iliac bones in such fashion that the two vertebral columns formed a V. The two pelves had nearly the same measurements, and the mammary glands were normally developed. The genito-urinary organs opened in a common triangular space which was separated from the single anal orifice by the perineum. The coccyx could be felt to be single. The external genital organs had a triangular shape. There was a single clitoris and a single urethral orifice in a common vestibule; but though the vulva was single, there were two separate vaginal canals. From physiologic signs it was evident that the rectum was single for a considerable distance up, and that there were two bladders." One of these sisters became pregnant. "The non-pregnant sister continued to menstruate and her general nutrition was unaffected, while the pregnant sister lost flesh." The labor at term was normal. "During the puerperium there was milk in the breasts of both sisters; in fact, the secretion was more marked in the one who had not been pregnant." The physical condition of the child is not stated. "These interesting phenomena in parabiosis," concludes the review, "throw some light on the causes of mammary activity in pregnancy and seem to show that they differ from the causes underlying the general nutrition of the body."

This case is not only a remarkable obstetric anomaly, but affords interesting suggestions as to the sexual physiology of such a monstrosity, upon which profitable observations might be made similar to those recorded of the more famous male Siamese twins.

## MEDICAL NOTES.

Proposed School of Tropical Medicine. — It is reported from New York that a graduate school of tropical medicine is soon to be established in that city in association with the New York Post-Graduate Medical School and Hospital.

Sale of Cigarettes in Utah. — It is reported from Salt Lake City that on March 18 the Utah Legislature passed a bill making it a misdemeanor to sell cigarettes or cigarette papers in that state. Apparently in that community cigarette-smoking is regarded as more of a menace to civilization than plural marriages.

Cholera at Honolulu. — During the week ending March 18, one new case of Asiatic cholera was reported at Honolulu, making a total of 27 cases since the outbreak of the epidemic there on Feb. 24. There were no deaths from the disease during that week.

Scarlet Fever at Bryn Mawr. — Report from Philadelphia states that, on March 15, three cases of scarlet fever were reported among students at Bryn Mawr College, and that in consequence two of the dormitories have been quarantined and all academic exercises suspended for ten days.

Award of Lannelogue Prize to Dr. Horsley. — A recent issue of *Nature* notes that the Lannelogue prize of a gold medal and 5,000 francs for the greatest contribution to the progress of surgery has been awarded to Sir Victor Horsley, F.R.S., of London.

Award of Fothergillian Medal to Dr. Mott. — In the issue of *Science* for March 17,

it is announced that the Fothergillian triennial gold medal of the Medical Society of London has lately been awarded to Dr. F. W. Mott, F.R.S., for his researches on the nervous system.

Address in Iowa by Dr. E. H. Smith. — At a meeting of the president, faculty and students of the State University of Iowa, in Iowa City, on March 8, Dr. Eugene H. Smith, Dean of the Harvard Dental School, made an address on "The Need of College-Trained Men in Dentistry."

An American Physician Killed in Mexico. — Report from Mexico states that on March 6, Dr. J. W. Wilson, an American physician formerly practicing in Tulsa, Okla., was killed in the assault by insurrectionists on Casos Grandes. Dr. Wilson was serving with the insurgent forces in a medical capacity.

Provisional Bequest to Massachusetts General Hospital. — The will of the late William H. Hart, of Boston, who died on March 10, was filed for probate last week. It contains a provisional reversionary legacy to the Massachusetts General Hospital, by which, upon the death of certain beneficiaries without issue, that institution may receive over $50,000.

Penalty for Disregard of Quarantine. — Report from Kingston, Jamaica, states that, on March 15, the captain of the United States auxiliary schooner *Adventuress* was fined $250 for entering that port without waiting for permission from quarantine officials. The *Adventuress*, which had been making a voyage of exploration among the West Indies and along the coast of South America, had last sailed from Cienfuegos.

Prizes for Dental Excellence. — An item in the monthly bulletin for February of the New York State Department of Health calls attention to the importance of instruction in oral hygiene in the public schools. "Recently, in an English school, prizes were offered for those children who could show at the end of three months the greatest improvement in the condition of their teeth." Perhaps such forms of physical excellence are more worthy of encouragement in this manner than proficiency in athletic sports.

Induced Cell Division and Cancer. — Messrs. R. J. Harvey Gibson (professor of botany), W. A. Herdman (professor of zoology), B. Moore (professor of biochemistry), J. Reynolds Green (lecturer on vegetable physiology), C. S. Sherrington (professor of physiology), in the University of Liverpool, desire to state that, in a volume just published by Messrs. John Murray & Sons, entitled "Induced Cell Division and Cancer," by Mr. H. C. Ross and Dr. J. W. Cropper, their names are quoted both in the preface and in the body of the work, and that, having had no opportunity of seeing the work, either in manuscript or in proof, any merits or responsibilities attaching to the statements made, or to the conclusions drawn in the book, do not belong to them.

The Seventeenth International Congress of Medicine. — The Seventeenth International Congress of Medicine will meet in London in the summer of 1913. The exact date is to be fixed by the International Permanent Committee, which will assemble for the first time in London, April 21 and 22 next, under presidentship of Dr. F. W. Pavy.

At the same meeting the list of sections of the Congress will be constituted. Any wishes or propositions concerning the arrangement of this list may be sent, up to the 1st of April, to the Honorable General Secretary of the Permanent Committee, Prof. H. Burger, Vondelstraat 1, Amsterdam, or to the Bureau of the Committee, Hugo de Grootstraat 10, The Hague.

The committee will be glad to receive, before the same date, and at the same addresses, possible suggestions and propositions concerning the organization of the Congress.

Recent Honors for Dr. Ehrlich. — Dr. Paul Ehrlich, director of the Institute for Experimental Therapeutics at Frankfort, formerly famous for his researches on the blood and on the theory of immunity, has lately been awarded numerous honors for his more generally familiar recent discovery of salvarsan in his investigations of the treatment of syphilis. A recent issue of the *British Medical Journal* states that he has received from the Emperor of Russia the Order of St. Anne, from the King of Spain the Grand Cross of the Order of Alfonso XII, from the German Emperor nomination to the Senate of the Kaiser Wilhelm Society for the advancement of science. He has also been made an honorary member of the St. Petersburg Institute of Experimental Therapeutics. These distinctions, though of course gratifying as recognitions of merit, are in themselves trivial compared with the satisfaction of service in the probable benefit of his discovery to humanity.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, March 21, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 46, scarlatina 49, typhoid fever 11, measles 151, smallpox 0, tuberculosis 74.

The death-rate of the reported deaths for the week ending March 21, 1911, was 20.97.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, March 18, 1911, was 275, against 241 the corresponding week of last year, showing an increase of 34 deaths, and making the death-rate for the week, 20.81. Of this number 139 were males and 136 were females; 263 were white and 12 colored; 179 were born in the United States, 93 in foreign countries and 3 unknown; 74 were of American parentage, 175 of foreign parentage and 26 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 42 cases and 2 deaths; scarlatina, 48 cases and 6 deaths; typhoid fever, 8 cases and 0 deaths; measles, 133 cases and 1 death; tuberculosis, 60 cases and 29 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 37, whooping cough 4, heart disease 35, bronchitis 3. There were 21 deaths from violent causes. The number of children who died under one year was 50; the number under five years, 70. The number of persons who died over sixty years of age was 70. The deaths in public institutions were 102.

DEATH OF MISS PILLSBURY. — Miss Grace G. Pillsbury, who died at Malden, Mass., on March 17, was formerly superintendent of nurses in the Addison Gilbert Hospital at Gloucester, Mass., and had also served for three years in the same capacity at the Danvers (Mass.) Insane Hospital.

A CENTENARIAN. — Mrs. Eliza Dix Upham, who died at Brookline, Mass., on March 12, is said to have been born on June 11, 1808, in Weston, Mass. Until a few months ago her health was reported to be excellent, and she was able to read without glasses. She had been twice married, and is survived by one son.

APPOINTMENT OF NEW PORT PHYSICIANS AT BOSTON. — It is announced that Dr. William H. Gay, of East Boston, who has served for the past ten years as assistant port physician of Boston, is to be promoted to the position of port physician and quarantine officer, recently made vacant by the appointment of its former incumbent, Dr. Paul Carson, to take charge of the medical inspection of public schools in this city. It is also reported that Dr. Francis X. Crawford, of Boston, is to be appointed as the new assistant port physician.

JOINT DENTAL MEETING. — A joint meeting was held in Boston last week by the Metropolitan District Dental Society of Massachusetts, the Odontological Society of Boston, the Tufts Dental Alumni Association, and the American Society of Dental Science. About 150 persons were present. The two principal addresses were made by Dr. John Winters Brannan, of New York, on "Dental Work at the Bellevue Hospital," and by Dr. Herbert L. Wheeler, of New York, on "Dental Hygiene on a Rational Basis."

SOME HEAVY MEN. — Joseph A. Dusahame, a Civil War veteran who died last week in the Soldiers' Home at Noroton, Conn., was reputed to be the heaviest man who ever served in the United States Army. At the time of his death he is said to have weighed 450 pounds.

At a recent meeting in Boston of a committee of the New England Fat Men's Club, that interesting organization which illustrates the humorous genius of the Yankee in making a club out of anything, Mr. C. H. Jackson, of Brockton, Mass., said to be the heaviest man in New England, is alleged to have demonstrated his present weight to be 535 pounds. Sir John Falstaff should be the proto-patron of this club.

NEW YORK.

REPORT OF NEW YORK STATE BOARD OF CHARITY. — The forty-fourth annual report of the State Board of Charities has just been made public. In it is urged state supervision of charitable institutions which do not receive public money. The work of private relief, the report says, is carried on mainly by corporations organized under the law to perform duties essentially public in their nature. The people of the state are entitled to know how these charitable creations of the state fulfil the functions for which they were created, and to be informed annually to what extent dependency exists within its borders and the methods of relief employed. Moreover, trust funds given for the aid of the poor should be examined from time to time by state authorities to insure the protection and proper use of such funds. The report states that an

investigation made last June showed that some of the smaller private hospitals in New York City which receive pay from the city for the care of public patients, besides other defects, were providing for the patients a much smaller cubic air space than the best authorities have considered necessary; and this resulted in the adoption by the board of more specific rules for the care of public patients by private hospital corporations generally. The Department of Public Charities in New York has, it says, two paramount needs: The extension of its facilities to relieve constant overcrowding, and the payment of better wages to hospital helpers in order to secure a higher grade of service. Mayor Gaynor is given credit for the additional appropriation in the budget of 1911, part of which is being used for increased remuneration for minor employees. The particular needs of the Bellevue and Allied Hospitals are stated to be the extension of the dispensary facilities of Gouverneur Hospital, now greatly overtaxed, and the addition of a new wing and a nurses' home to Harlem Hospital. In this connection it is pointed out that New York's present system of administering its public hospitals, through three separate departments, is archaic and illogical. The board again urges its recommendation, made to the legislature in 1910, for the establishment of a farm colony for tramps and vagrants. The statistics given in the report show that there has been an increase, since 1906, of 9,000 in the number of dependent persons of all kinds cared for by the state, the total number now being 78,384. The numbers in the various classes are specified, after which it is mentioned that during the year outdoor relief was reported to have been given to 43,324 persons in the forty-nine cities of the state, at a cost of $373,513. The per capita rate of expenditure by inhabitants of each city is given, ranging from 1 cent in Elmira to 58 cents in Middletown, where the overseer of the poor reports 19 out of every 100 of the population as receiving relief.

Memorial Gift. — Mrs. Siegmund Neustadt, widow of a New York banker, has given, as a memorial to her husband, $30,000 to the Young Men's Hebrew Association for a finely equipped building at the association's vacation camp at Cold Spring on the Hudson.

Meeting of Women's Medical Society. — The fifth annual meeting of the Women's Medical Society of the State of New York was held at the Academy of Medicine on March 9 and 10, and the sessions were closed with a dinner at the Hotel Leonori, at which no mere man was admitted.

Scarlet Fever at Little Falls, N. J. — Three of the public schools of Little Falls, Passaic County, N. J., have been closed on account of an epidemic of scarlet fever. This is the second outbreak of the disease in the village since the autumn, and more than fifty children have been attacked.

Club House for Bellevue Nurses' Alumnæ Association. — Mr. and Mrs. William Church Osborn have announced that, on May 1, they will present to the Bellevue Nurses' Alumnæ Association a commodious home and club house on 26th Street, opposite Bellevue Hospital, as a memorial to Mr. Osborn's mother, who was one of the first persons in this country to interest themselves in training schools for nurses.

Cerebrospinal Meningitis on Shipboard. — On two successive days, March 12 and 13, steamships arrived at quarantine with passengers ill with epidemic cerebrospinal meningitis on board. The first of these was the *Patris*, from Piræus, Greece, with five persons suffering from the disease. During the voyage six others had died from it, the diagnosis being confirmed by autopsy in the case of two of them, whose bodies were still on the ship. On the second steamship, the *Martha Washington*, from Trieste, there were four cases of the disease, and one had died during the voyage. All the patients were promptly taken to the Hoffman Island Hospital, where they were successfully treated by means of Flexner's serum. Health Officer Doty states that he has found that the great majority of cases of cerebrospinal meningitis coming to the port of New York in the last few years have been among Greeks.

The Relation of the State to Poliomyelitis. — The possibility of the control of epidemic anterior poliomyelitis by the state was discussed at the March meeting of the Society of Medical Jurisprudence. The principal paper of the evening was read by Dr. B. Sachs, who contended that the state authorities should consider the manner in which the epidemic spreads from town to town. Provision should be made, he said, for tapping the spinal column, and the fluid should be sent to state laboratories for diagnosis. Dr. Flexner had found that the cerebrospinal fluid from monkeys experimented on showed an opalescent

appearance before paralysis developed, but later became normal. The state should require that all cases be reported, and schools should be closed where more than one case occurred. Dr. Smith Ely Jelliffe said the infection was carried by some form of contact, either mediate or intermediate. The patient himself was not so likely to communicate the disease as the person who came in contact with him. We might have to look in another direction for the means of communication. Little progress was made in the prevention of yellow fever until transmission by the mosquito was discovered, and here also some such carrier would possibly be found. Dr. H. W. Berg was decidedly of the opinion that our knowledge of the disease had not yet reached a point where the state could well be called to take its prevention in hand. At present, he said, very little could be done in the way of prevention. The victim was often overwhelmed as by a thunderbolt. A perfectly healthy child might go to bed without a symptom of illness and in the morning be paralyzed. Dr. Flexner, by examining the fluid of his monkeys every day, was able to find the virus before paralysis took place, but he had artificially infected the monkeys and knew that the virus was there. In the human subject there was no symptom apparent before the onset of the disease, and the damage was done when the paralysis developed. We certainly had no right to enter the spinal column of a healthy child because another child on the next block had been paralyzed. As to closing the schools, it should be borne in mind that the epidemic in New York was in the summer, when the schools were not in session. There was no connection whatever between the disease and the schools. Dr. Flexner's infected monkeys were in the same cages with other monkeys, yet not one of the latter contracted the infection. In the epidemic of 1907, not a single instance came to Dr. Berg's knowledge where one member of a family gave the disease to another. The contagion was not direct; there must be a carrier for the infection. More time should, therefore, be given to the medical profession for investigation of the disease before plans were made for its prevention and supervision by the state.

7. GOLDMANN. *The Climatic Indications of Egypt in Otology and Laryngology.*

3. Seibert has demonstrated clinically that a sufficiently large hypodermic injection of salicylic acid or salicylate of soda (10% salicylic acid solution in sesame oil or 20% watery solution of sodium salicylate) can inhibit the pathogenic action of rheumatic organisms in the human body in a few hours without causing toxic symptoms. By first injecting a small watery solution of cocaine, gr. ½, all discomfort to the patient can be avoided.

5. Pilcher and Pilcher report an interesting case of chyluria. Cystoscopic examination showed that the chylous urine was being secreted from the left ureter only. Filariæ sanguinis hominis were found in blood smears taken at midnight every night. Six tenths of a gram of "606" was given subcutaneously; for the first twenty-four hours after the injection, the urine remained unchanged; during the succeeding forty-eight hours, it became perfectly clear (first time in seven months); suddenly from the sixty-eighth to the seventy-second hour it became chylous again and contained large numbers of seemingly dead filariæ, embryonic and adult; after the seventy-second hour the turbidity ceased and no filariæ were demonstrable either in the urine or the blood.

6. Meisenbach has had good results with artificial rubber muscles as temporary reinforcements for muscles damaged by poliomyelitis. The method is chiefly applicable to the ankle, knee, wrist and shoulder. [L. D. C.]

4. The following are important points brought out in Sherk's very thorough paper on abdominal injuries. A stomach distended with food, fluid or solid, or with gas, is more easily bruised or torn than an empty one. Therefore, the relation of the time of the last meal and stool to the time of the injury is of importance. According to most authorities, the liver is the most commonly injured of the solid viscera, except the kidneys. In the author's series, however, the spleen received the greatest number of injuries. Splenic injuries are more common in tropical countries where malaria exists, because an enlarged spleen is more liable to injury than a normal one. Most of the tears occur on the inner surface even when the injury is distinctly on the outer surface. The normal spleen is most likely to rupture at the height of its functional activity, i. e., some hours after eating. In most cases, injury to the stomach is accompanied by injury to the liver also. The upper end of the jejunum and lower ileum are affected in 75% of all intestinal injuries, the duodenum in 5%, the large intestine in a little over 3%, while 17% covers other parts of the small intestine. Rupture of the gall bladder is rare and occurs only with severe liver injuries, especially when stones are present. According to Deaver, the cystic duct is the part most commonly affected. Early vomiting is not of much importance, but persistent or late vomiting is usually indicative of serious injury. In large tears of the stomach, vomiting is likely to be absent. Distention is generally a late accompaniment of trauma of abdominal viscera. When it appears early, to any extent, it usually means gross injury, with extensive extravasation of intestinal contents, both fluid and gas. The distention that comes later and comes on gradually is the result of intestinal paralysis and is one of the most important signs in diagnosis. Auscultation to ascertain the presence or absence of peristalsis here is of vast importance. The primary symptoms of injury of the mesentery are those of hemorrhage. Hiccough often suggests injury to the diaphragm. There are no symptoms that are pathognomic, most of them being common to all injuries, but, in general, progressively increasing shock indicates trauma of the solid organs, while early symptoms of peritonitis follow tears of the intestine or stomach. Pain as an initial symptom is unimportant only in that it calls attention to the possible site of the trauma.

15. Rous and Murphy have succeeded in implanting bits of the sarcoma of the fowl into the embryonic membranes in the growing chick egg, and also, a fact which is of far vaster importance, have succeeded in getting transplants in the same kind of egg embryos by means of a cell-free filtrate of this same sarcoma. This work ought to have great weight if such transplants can be carried out in other experimental animals. [E. H. R.]

10. Brown, W. H. *Malarial Pigment (So-Called Melanin); Its Nature and Mode of Production.*

9. Dr. Mary Rowley-Lawson reports the result of a very careful and exhaustive study of the estivo-autumnal parasite. Her article is accompanied by a large number of micro-photographs and some colored plates. These photographs and plates are very convincing and seem to justify the writer in concluding that the very young ring-form parasite has no capsule; the macrogamete has one during its development and sexual activity; while the microgametocyte has it only during its development. The fact that the crescent is more resistant to quinine than the other varieties of malarial parasites might be explained by the presence of a capsule which appears to protect the parasite, certainly during the sexual phase and probably during the "resting" period (when not undergoing sexual changes). The youngest form of ring parasite shows no evidence of encapsulation.

*The sexual cycle* of the crescent may occur in the circulating blood of its human host. This cycle is probably very rapid, for practically the whole cycle can be seen in a few smears taken from one puncture. The microgametocyte, or male, develops a flagellum (microgamete) which, *after the parasite has assumed the crescentic phase*, leaves the body of the parasite and enters the body of the macrogamete, or female, *during its existence as a round body*. Fertilization is then accomplished. The microgametocyte, after the escape of the flagellum, shows evidence of degeneration and is probably cadaveric.

After fertilization, the macrogamete assumes the crescentic form, reaches the reproductive phase and undergoes sporulation, the product of which appears to be the small ring-form parasite. Renewed infection of the red cells then takes place. [R. I. L.]

7. JONES, E. D. *Primary Sarcoma of the Appendix.*
8. BRYAN, R. C. *Stone in the Ureter.*

1. Mayo believes that for patients over forty years of age hysteromyomectomy is undoubtedly the operation of choice and after the age of forty-five there will be few exceptions to this choice. According to Bland-Sutton, 10% of women who require operation for myomata after they have reached fifty years of age will have associated with it malignant disease of the uterus.

2. Bruce cites a class of cases of inflammatory disease, generally a perisigmoiditis or colitis, in which many of the signs of malignancy, such as obstruction, loss of weight, tumor and pain, are present, but which show microscopically only chronic inflammation.

3. Pilcher considers that the expectant treatment is indicated in cases of slight injury to the kidney in which there is only moderate or transitory hemorrhage of short duration. Operation is contra-indicated when both kidneys are extensively injured. Operation is strongly advised when there is progressive, recurrent or persistent hemorrhage; also, when infection has taken place.

6. Rubin's very interesting and complete article on the functions of the great omentum is summarized in brief as follows: The omentum has no spontaneous motility. Its displacements are due to intestinal peristalsis, intra-abdominal tension and the static condition of the stomach, colon and small intestine. The omentum has no demonstrable chemotaxis; the amount of intraperitoneal fluid, gas in intestine and suction action of the diaphragm explain the apparent chemotaxis. The omentum has no intelligent and spontaneous protective rôle. It cannot supply vitality to necrotic organs, nor vascular supply to those deprived of their circulation. The usefulness of the omentum in inflammatory lesions of the abdomen depends upon its power to form adhesions which isolate and render innocuous toxic products, its power of absorbing and eliminating toxic products or destroying them by virtue of its phagocytic elements, but when contrasted with its sequelæ, intestinal obstruction, pain, etc., its beneficence is over-balanced. The chief functions of the omentum are those of any other mesentery, namely, the fixation of the viscera and vascular supply. When the omentum is found adherent to an intra-abdominal tumor the probabilities are that the mass is inflammatory and not neoplastic. If the tumor is neoplastic, it has probably undergone inflammatory changes. This is an important point in diagnosis. Too much should not be expected from grafts of the omentum. A detached piece rapidly becomes necrotic and is useless. Only intact portions produce serviceable adhesions. [E. H. R.]

9. FFRENCH, E. G. *A Report on Three Cases Treated with Ehrlich's Specific for Syphilis.*

2. Haslam presents an interesting historical review of the growth and development of the surgery of stone in the male bladder.

3. Stockman does not believe that the condition first described by Dercum as "adiposis dolorosa" is a definite clinical entity, but that many of the symptoms described as belonging to this condition are simply due to the presence of fat alone. He goes on to describe what he terms a very common affection in which the presence or absence of fat is but an incident which consists of a chronic subcutaneous fibrosis. It is apt to be the result of acute rheumatism, influenza or general gonococcal infections. Microscopic examination shows a fibrosis of the subcutaneous tissues, regardless of the fat, with peri- and endo-arteritis of the small vessels and an interstitial inflammation of the small nerve twigs. The symptoms are aching pain, stiffness, neuralgias, numbness, fatigue, lack of vigor and energy, and others. The thickenings are readily felt and usually tender on pressure. Treatment consists of carefully regulated massage in thin people and getting rid of the fat by diet and then massage in fat people. This somewhat fantastic although ingenious statement will require further confirmation before it can be accepted.

4. Alexander discusses the work previously done on the use of leucocytic extract in various conditions, but expecially tuberculosis, and reports his own experiences with ten cases of infections due to various organisms. His results are apparently entirely negative. He found that the injections of leucocytic extract produced a great leucocytosis in the blood which is exactly the opposite of the findings of Floyd and Lucas in their work on the use of the leucocytic extract in pneumonia in children. [J. B. H.]

### FEB. 25, 1911.

8. *HASLAM, W. F. *The Lettsomian Lectures on a Review of the Operations for Stone in the Male Bladder.*

2. Windle presents a long and elaborate article, illustrated with many sphygmographic tracings, on the use and action of digitalis in heart disease and dropsy associated with fibrillation of the auricles. Fibrillation of the auricles is a term used to describe that condition of absolute cardiac irregularity with a ventricular venous pulse in which there is an entire absence of normal auricular contraction, but instead its musculature is in a state of unceasing tremulous movement. Such cases resulting from old rheumatic lesions respond most actively to digitalis; in other cases, apparently similar, digitalis has apparently little effect. The writer discusses the causes of this discrepancy in this article. In his opinion the difference in action of this drug depends largely on the amount of associated kidney involvement.

4. Morton, discussing the use of radium in cancer, believes that its chief value is in aiding other methods of treatment and not in excluding them. If it is going to act beneficially, it does so at once within three to four days.

8. *Cf. Lancet*, Feb. 25, 1911. [J. B. H.]

## DEUTSCHE MEDIZINISCHE WOCHENSCHRIFT. No. 7.

### FEB. 16, 1911.

1. AHLFELD, F. *Puerperal Auto-Infection.*
2. *BITTORF, A. *Herpes Zoster and Renal Colic: A Contribution to the Knowledge of Head's Zones.*
3. *SCHERSCHMIDT. *The Treatment of Sleeping Sickness with Arsenophenylglycin.*

12. Sigalin, M. *Breathing Gymnastics on a Psychic Basis.*
13. Schall, M. *Technical Novelties in the Domains of Medicine, Public Hygiene and Cure of the Sick.*

2. Bittorf reports on the occurrence of herpes zoster with painful diseases of the internal organs. This herpes appears in the spots known as Head's zones. He reports a case of hydronephrosis with a herpes zoster in the region of the eleventh dorsal segment. In other cases in which there was not a herpes there was hyperalgesia in these zones. In aortic disease sensitive areas can be found on the ulnar side of the left forearm.

3. Scherschmidt has tried Ehrlich's arsenic preparation, arsenophenylglyzin, in cases of sleeping sickness. This drug was heralded as being more satisfactory than atoxyl, after the use of which people frequently relapse. He has not found that this new preparation has fulfilled in man the expectations which seemed justifiable from animal experimentation. It is a dangerous drug to use and unless it is used for its full effect the results are not satisfactory. He thinks that success against this disease will depend on sanitation and elimination of the flies. [C. F., Jr.]

2. The author explains his operation which is especially designed for the old and feeble. At the first operation under local anesthesia a suprapubic vesical fistula, of fairly large proportions, is made. The bladder is then drained by a permanent catheter and washed out several times a day. When the urine is clear, the prostate is removed. This is done under a local anesthetic of cocaine or novocain. The author reports a series of cases. [J. L. H.]

Zeitschrift für Klinische Medizin. Band 72.

Heft. 1 and 2.

1. *Sahli, H. *Advances in Sphygmobolometry or Diagnosis of Pulse Energy.*
2. Ziegler, K. *Clinical and Anatomical Paper on the Teaching of Chronic Lymphatic and Myeloid Leukemia.*
3. *Falta, W., Newburgh, L. H., and Nobel, B. *Interrelation of Glands with Internal Secretion. Relation of Overfunction to the Constitution.*
4. *Eppinger, H., and Hofbauer, L. *Circulation and Diaphragm.*
5. Jarussow, S. *A Reinfection in Relapsing Fever, and Its Influence on the Course of the Disease.*
6. *Bondi, S. *The Use and Action of Acetylsalicylic Acid in Typhus Abdominalis.*
7. *Bondi, S., and Katz, H. *Experimental Communication on Aspirin.*

1. Sahli regards sphygmobolometry — a method for carefully measuring the energy of the pulse — of greater importance than estimates of blood pressure and the form of pulse waves can possibly be, as this measures the power and capability of the heart; the others show only its attainments. The method is intricate and will not be described. The present article modifies radically the method which appears on this subject in the 1909 (fifth) edition of his "Lehrbuch"; it shows two principal and important changes, first taking into account the amount of air employed in the armlet, and, second, the introduction of a spirit manometer held in an horizontal position (to be standardized by a mercury one) which reduces inertia errors to a minimum.

3. The authors continue their study of glands with internal secretion. On administration of *adrenalin* the most constant effect is increase in blood pressure, which may be considerable and of moderate duration. Pulse frequency, usually increased, is, however, variable and may be irregular. Glycosuria produced by injection of adrenalin is independent of occurrence of increased blood pressure; if adrenalin fails to cause glycosuria, previous administration of atropine usually succeeds in bringing this about; pilocarpine (.01), on the other hand, inhibits the occurrence of adrenalin glycosuria. The contrary effect of these two drugs is here of particular interest in that neither of them has any evident effect on alimentary glycosuria, thereby pointing to different factors as cause of these two forms of glycosuria. Adrenalin always causes increased sugar output in active diabetes, without necessarily concomitant diuresis. In tetany, adrenalin brings on an attack. As adrenalin was given always subcutaneously at .001-gm. dose, and as the glycosuric, diuretic, leucocytic and pressor effects were obtained apparently without relation to each other, the authors conclude that differences in the organism alone explain the results.

*Thyroid* extract given over a period of three days always caused increase of pulse-rate and, except in diabetes, diminution of blood pressure. In the aglycosuric period of diabetes, thyroid medication causes glycosuria and shows little effect during the active stage, an opposite effect from adrenalin. A relative increase in number of mononuclear blood cells was almost constant. Headache, pain in the limbs, tremors, loss of weight and psychoses were less striking and less constant effects of thyroid administration.

*Pituitary* extract has no effect on glycosuria; its diuretic effect seems to be parallel with adrenalin.

The manifold and dissociated effects of adrenalin and thyroid medication upon the body are as yet inexplicable.

4. By use of the plethysmographic method the authors show graphically increased outflow of blood from the lower extremities when the diaphragm stands high; a diminished flow when low. This fact is of importance in relation to the position of the diaphragm in such conditions as emphysema and pleural effusion. The difference seems to depend upon changes in abdominal and intrathoracic pressures and also in size of the foramen quadrilatum in the diaphragm.

6. Bondi, after investigation on a number of cases, recommends aspirin in 0.25-gm. doses, two or three times a day, as antipyretic in typhoid fever. He finds that in these minute doses aspirin is almost specific in action, reducing temperature almost invariably within an hour and causing a reduction for from two to six hours of between 1.5° and 3° C. For comparison he used as control a corresponding dose of salicylic acid, of diaspirin, of diplosal, of triacetin and the full tub; none of these agents had nearly the antipyretic effect of aspirin. The author has never seen collapse from these small doses; sweating and chilliness occasionally.

7. Bondi and Katz, investigating the action of aspirin, determined (1) that it is practically unaffected by the gastric juice; (2) that it is very slowly split by an alkaline medium or artificial intestinal content; (3) that it is never excreted as aspirin, but as salicylic acid; (4) that aspirin in alkaline medium is *quickly split* by liver extract. Therefore, they conclude that aspirin is absorbed as such, is split in the body tissues and excreted as salicylic acid.

4. KOHNSTAMM, O. *The Nature of Hysteria.*
5. LAQUEUR, A. *The Therapeutic Use of High-Frequency Currents.*
6. FRIEDBERGER, E. *The Nature and the Importance of Anaphylaxis.*

2. Huber observes that while it is well known that uncomplicated tertiary lues of internal organs is often attended with obstinate fever, it is less well recognized that such fever has characteristic properties and is of diagnostic value. It is remittent or intermittent in type and yields promptly to antisyphilitic treatment. The writer reports a case of syphilis of the liver with a characteristic temperature chart. The patient had suffered attacks of severe pain in the right hypochondrium with chills and fever for three years and was operated upon for gallstones but none were found. The liver was enlarged and histological examination of a piece showed gummatous nodules, Wassermann reaction positive. One injection of "606" cured the man and put an end to the fever. [L. D. C.]

REVUE DE MÉDECINE.

1. *BARBÉZIEUX, G. *Beri-Beri: Its Pathogenesis and Treatment.*
2. LABBÉ, H. *Ammoniacal Nitrogen in the Formation of Urea in the Organism. II.*
3. *CECIKAS, I. *Digestive Tests by Diet.*

1. The author claims that beri-beri should not be classified as a disease entity. It has no definite pathology, etiology or symptomatology. It is rather a syndrome which manifests itself in predisposed individuals, in a word, in those with the "neuro-arthritic diathesis." The salts of sodium, the salicylate in particular, seem to exercise a great influence, not merely on the symptoms, but in cutting short the course of the process.

3. Cecikas does not advocate the use of the Schmidt-Strassburger diet as a test of intestinal function. This diet, he claims, is too bulky for the average individual, especially for those suffering from inanition, who are often subjected to such a test. The latter, while rejecting the diet in an undigested form in the early stages, adjust their organs to the overwork, so that normal digestion is evidenced in the latter part of the period. This unevenness of results is unsatisfactory. He advises a diet consisting of carbohydrate 300 g., albumin 100 g. and fat 100 g. By this means a lighter, more constant and more agreeable bill of fare can be prepared. [L. H. S.]

REVUE DE CHIRURGIE.

2. WEITZEL. *The Treatment of Cranial Wounds in Advanced Guards.*
3. *IMBERT, L., AND DUGAS, G. *The Remote Prognosis of Dislocations of the Shoulder.*
4. MONOD, C., AND VANVERTS, J. *Documents and Remarks on the Treatment of Arterial and Arterio-venous Hematomata.* (Conclusion.)

1. From a summary of sixty-seven cases of cholecystitis operated in the course of typhoid fever or during convalescence, Quénu concludes that in such cases cholecystectomy may be an operation of necessity but is never an operation of choice.

3. From a study of fifteen cases, the authors conclude that simple subcoracoid dislocations of the shoulder, promptly reduced, are followed by functional disturbances and phenomena of pain for several months. This temporary incapacity may become permanent, exceptionally on account of traumatic paralyses of the cords of the brachial plexus, much more frequently from scapulo-humeral peri-arthritis. Probably it is more often due to peripheral neuritides than to inflammation of the sub-acromial bursa. [R. M. G.]

1. ALESSANDRINI, P. *A Contribution to the Study of the Relations Between the Lipoid Content of Serum and the Wassermann Reaction.*
2. *GAVINI, G. *A Contribution to the Question of the Practical Value of the Wassermann Reaction in Syphilis.*
3. PONTANO, T. *An Experimental Contribution to the Knowledge of the Metabolism of Nitrogen and Uric Acid in Gout.*
4. FULCI, F. *On the Experimental Production of Endocarditis.*

2. Gavini concludes as follows from an exhaustive study of the Wassermann reaction in thirty-six cases of syphilis: A positive (strong) reaction is pathognomonic; if persistent, prognosis should be guarded. A doubtful reaction is of diagnostic value if it is confirmed by history and physical signs and other diseases can be excluded; its prognostic significance depends upon the stage and course of the disease and the length of treatment. A negative reaction does not absolutely exclude syphilis. There is a close relation between mercurial treatment and the Wassermann reaction and the test is a good index of the effect of mercury. [L. D. C.]

1. In 39 out of 67 cases of acute or chronic urethral blennorrhagia, Lofaro cultivated the gonococcus from the circulating blood.

2. From bacteriologic study of 95 operative cases, Duse concludes that Grössich's method with tincture of iodine is not inferior to other procedures for disinfection of the skin. [R. M. G.]

## Obituary.

### HENRY PICKERING BOWDITCH, M.D., LL.D., HARV.

THE death of Dr. Bowditch, which came at the end of a day of quiet and peaceful unconsciousness,[1] brought to a close a strong, courageous and useful life, marked from first to last by work accomplished, friendships formed and strengthened and honors fairly won.

It is now fully ten years since his serious malady (paralysis agitans) began to fetter his strong limbs, and for a long time past he had wished for the release of death. Activity and industry had been synonymous for him with living and breathing, so that the thought of being grasped in the tightening coils of this intangible and inexorable illness was intolerable to his spirit and he faced his fate unreconciled. In later years, however, he accepted the situation frankly and bent himself to recognize the many sources of happiness

[1] Dr. Bowditch became unconscious during an apparently quiet sleep on the day before his death and did not regain consciousness again, though he came to himself sufficiently to show some signs of response to simple requests. He had a slight facial palsy but no paralysis of the limbs. The respiration became very slow, sinking for a time to the rate of four a minute. The probable diagnosis was thrombosis of a vertebral or the basilar artery, due to his long-standing arteriosclerosis.

that still remained to him; and if his early attitude was characteristic of one tendency of his strong nature, another side came out quite as clearly in his gentleness and his readiness to appreciate the benefits that the hands of affection heaped about him.

Fortunately, the quality of his mind remained unchanged throughout his illness. To the end he retained a keen interest in public and private matters, and his sense of fun never deserted him.[1]

Dr. Bowditch came fairly by his good qualities, — his fidelity, his intelligence, his outspeaking honesty and fearlessness, and his public spirit. His ancestors on both sides were Essex County people who represented New England at its best. His grandfather, Nathaniel Bowditch, began his career by working his way before the mast, but long before his death he had become a very distinguished writer on navigation and mathematics, a man of international reputation. Nathaniel's second son, Ingersoll, the father of Henry Bowditch, was a successful merchant long honored for his integrity, good judgment and generosity. Mrs. Ingersoll Bowditch was the daughter of Benjamin R. and Mary P. Nichols, of Salem, and granddaughter of the fearless and stalwart Col. Timothy Pickering,[2] Secretary of State under Washington.

Henry Bowditch was born [4] and bred in Boston, and the friends who knew him as a boy still have vivid memories of the house on Summer Street, nearly opposite the end of Chauncy Street, which his father occupied for many years, in the day when that portion of the city was delightful with shade trees and sunny gardens and still boasted a few detached houses of colonial build.

Bowditch entered Harvard as an undergraduate in 1857 and was graduated with his class in 1861. In the autumn of that year he entered the Lawrence Scientific School and began to study chemistry, but the Civil War was breaking out and the two Bowditches, Henry first, Charles nineteen months later, enlisted for the field. Henry joined the First Massachusetts Cavalry as second lieutenant in November, 1861. His cousin, Nathaniel Bowditch, who fell at the battle of Kelly's Ford in March, 1863, and many other Boston men, also became members of this gallant regiment. Charles' appointment as second lieutenant, Fifty-Third Massachusetts Volunteer Infantry, dated from May, 1863, two months after his cousin's death. This was the beginning of four years of military service for Henry Bowditch, interrupted only by a furlough covering the winter of 1863, to admit of his convalescence from a bullet wound in the arm received while he was leading a charge at the action of New Hope Church. In March, 1864, he was honorably discharged with the rank of captain, to re-enter the service as major in the Fifth Massachusetts Cavalry (colored).

War and the army were both obnoxious to him except for the end they sought, but to this end he was ready and willing to devote himself. His army experiences made a deep impression, the effect of which came out incidentally in many ways, but with his characteristic reserve, which was stronger than at once appeared, he found it difficult to talk about them.

Major Henry L. Higginson well remembers Dr. Bowditch as he then appeared, a handsome, refined and home-bred looking youth, with a fondness and faculty for keeping face clean and clothing neat at periods when those attributes were a rarity. He remembers him also as being an upright and fine officer, often reserved and even unbending in his manner but unflagging in his faithfulness and unflinching in his courage. One day as they rode side by side through Sharpsburg, after the battle of Antietam, they talked together about the pains and pleasures of the soldier's life. Major Higginson said that he enjoyed it very well and had half a mind to make it his profession, but Bowditch declared that his feelings were the reverse of this and that he longed for the time when he could devote himself to scientific labors.

The First Cavalry played an active part in a number of engagements during its long service. It was not actually engaged at Gettysburg, but officers and men sat in their saddles through the long day as a part of the reserve column, waiting to be called out and Dr. Bowditch entertained himself by counting the discharges of the cannon from one or the other side as they fell upon his ear, and found them to recur about once a second through almost the entire day.

He resigned his command on June 3, 1865, soon after the close of the war, and in the autumn of the same year took up his scientific studies where he had left them off, re-entering the Lawrence Scientific School and taking Prof. Jeffries Wyman's admirable course in comparative anatomy. Later in the year he began in earnest to study medicine at the old North Grove Street school. He was graduated in medicine in 1868 (having received his A.M. in 1866) and immediately went abroad to study physiology, first at Paris, under Claude Bernard; then at Bonn, and finally at Leipzig, under the able, warm-hearted Professor Ludwig, then in the full tide of life and work. This truly great man and fine teacher became a personal friend of Bowditch, as of many others of his pupils, making them joint investigators and publicists with himself and giving them a generous share of credit. The writer was a special student in Leipzig during a portion of this time and gained a realizing sense of that brimming life of Ludwig's happy family of students, all destined to stand high among the world's teachers of their day and generation. Cyon,

[1] Only a week before his death Dr. Bowditch told the writer with great amusement the following story of his little grandson: The child, it appears, having been brought to pay a visit to his grandfather, sat watching his helplessness for a time and then asked him, "Are you sick?" On getting an affirmative answer the next question was, "What did you eat?"

[2] Deacon Timothy Pickering, father of Col. Timothy Pickering, had given evidence of the family boldness and patriotism by addressing to King George III an open letter (published in the *Essex Gazette* of Nov. 7, 1769) in which, after deploring the wasteful expenditure of the people's money by the royal government on needless "Pride and Luxury," he calls vigorously for economy and a redistribution of the taxes in favor of the poor. "I have," he writes, "an income of but eighty pounds sterling a year, including my own hands' labor; nevertheless I am freely willing to pay one-quarter part till my Public Debts are paid."

[4] Dr. Bowditch was born April 4, 1840, and died March 13, 1911.

Lauder Brunton, Uskimowitch, Mosso, Lankester and Kronecker were there, — all thereafter warm friends of Bowditch, — and Lépine, well-nigh the first Frenchman to show himself desirous of tasting the scientific fare that Germany was offering the world. First and last there were many other noted students, from Germany, Switzerland, England, Russia and other lands. The outbreak, in 1870, of the Franco-Prussian War stirred Leipzig profoundly and summoned several of these workers to their homes. Bowditch remained for a year longer, and when he returned, in September, 1871, it was with Selma Knauth, the daughter of Franz Theodor and Fanny Elizabeth Knauth, of Leipzig, as his wife, at whose hospitable home he had been long received as a welcome guest. It had been an eventful and notable two years that he had spent in the quaint old town, and he was never weary of talking over the pleasant memories of his stay. Professional trophies, too, he brought back with him, for he had done, in company with Ludwig, several pieces of excellent and important work upon the nerves and muscles of the heart, which were described soon after in the publications of the Leipzig Institute and soon were widely read. For a number of years afterwards the heart's action remained a favorite object of Dr. Bowditch's study.

It may well be believed that Dr. Bowditch arrived in Boston full of hope and vigor and ready to infuse new life into the study and teaching of physiology in his native land. He brought to this work fine traditions, the sense of responsibilities well met, the memory of inspiring friendships, the glow of German zeal, the power of German methods.

Dr. Holmes was still professor of physiology as well as of anatomy at the Harvard School, and Bowditch was made assistant professor of physiology and entered on his duties in September, 1871. In 1876 he was made full professor.

Good physiological laboratories in the German sense, that is, places where not only the professor himself could work, but where all who really wished to carry out researches, great or small, might find apparatus, materials and, above all, help, sympathy and discriminating criticism, were then practically unknown in the United States. Dr. Bowditch had strongly marked administrative gifts, a high sense of liberality and hospitality, and a remarkable mechanical inventiveness. To these qualities he could now add a knowledge of what research and what adequate laboratory equipment really meant. In the course of his professional career he founded successively three such laboratories in the three buildings to which he followed and guided the fortunes of the school, and the list would be a long one of the men who found in them the hand of welcome and the wise voice of counsel ready at their need.

As a lecturer Dr. Bowditch was clear and incisive rather than brilliant, but his methods were so well chosen, his arrangements were so orderly, his demonstrations so effective, he knew so well just what he wished to say, that he had little difficulty in holding the attention of his audience. The quality of his mind well fitted him for a teacher, for while ready to advance when the occasion called for progress, and entirely capable of taking a radical attitude in scientific as in public matters, yet his power of criticism and the distinctly judicial character of his mind inclined him to scrutinize the new and to conserve the old, and this tendency grew in him with his years. Most important point of all, he was a good teacher because he remained ever a good student. He was not, indeed, a prolific investigator in the largest sense, yet he never ceased experimenting and taking part in the experiments of others, and so kept his powers of study always fresh.

His best original contributions, besides those already mentioned, were his two prolonged studies into the laws of the growth of children; his demonstration of the non-fatiguability of nerves; the nature and modifications of the knee-jerk. But of lesser investigations there were many. Whatever he did was well and accurately done and his conclusions rarely courted the contradiction of his colleagues.

He did also an immense service to the cause of physiology, not only of this state, but of the country, in helping to resist the frequently recurring attempts to secure legislation unfavorable to the experimentation on animals absolutely required for medical research. Thoroughly humane himself, and warmly interested in the work of the Society for the Prevention of Cruelty to Animals, he saw that the first duty of humanity was to seek the amelioration of the lot of men.

In the faculty room of the Medical School his counsel became at once recognized as indispensable, and from first to last, when he rose to speak, he was listened to almost as a judge delivering his carefully balanced charge. He was appointed Dean June 25, 1883, immediately succeeding the much-loved Dr. Calvin Ellis, and it would be hard to imagine that difficult position filled with greater dignity and fairness or with a better sense of the work the school might do.

When it came to the question of new buildings, an undertaking of great risk, the fact that he was for it weighed heavily in its favor. His help in drawing plans for these extensive buildings was gladly sought and welcomed and it is well known that it was to his energy and courage, in association with those of his long-time friend, Dr. John Collins Warren, that the eventual securing of the building fund was mainly due.

In 1893 he resigned the position of dean. In 1900, feeling the shadow of illness beginning to creep over him, he began to withdraw from active work, and in 1906 he resigned his professorship altogether.

Dr. Bowditch's activity was by no means limited to his labors in behalf of physiology and medicine. The same sense of public obligation that sent him to the war led him to accept other positions of usefulness, such as member of the Boston School Committee, trustee of the Boston Public Library and of the Adams Nervine Asylum,

and president of the Boston Children's Aid Association, member of the Special Joint Committee on Health of the American Social Science Association, member of the Committee of Fifty to Investigate the Liquor Problem. He was also one of the original founders, with Dr. Weir Mitchell and Professor Chittenden, of the American Physiological Association, and coadjutor of Prof. W. T. Porter in establishing the *American Journal of Physiology*.

Numerous honors came to him in due course; degrees of Letters, or of Science, from the universities of Edinburgh (1898), Cambridge (1898), Toronto (1903), Pennsylvania (1904), Harvard (1906), besides various recognitions of more private sorts.

One of the last times that he appeared in public was in Sanders Theater at the ceremonies of dedication of the new Medical School buildings. The occasion was a memorable one, and Dr. Bowditch's impressive figure, clad in the scarlet robes of his Edinburgh doctorate, and seated at the front of the platform, side by side with Dr. Warren, made a fitting center to the striking scene.

A word must be said in closing about Dr. Bowditch's private and social life. Strong as was his sense of public obligation and of public trust; grave and even stern as his expression, speech and manner could become when occasion seemed to him to call for gravity or sternness, he had nevertheless a side of gaiety and lightness without knowing which it was impossible to know him. Whether as host at his own table or as guest at a friend's, on every occasion — and many were found — when his hearty laugh had an excuse for making itself heard, — as kite-flyer, mountain climber, inventor, photographer, old furniture maker and repairer, — in all these capacities, and many more, though each pleasant toil was marked with the never-wanting stamp of fidelity, thoroughness and honesty, he showed a humor, kindliness and charm which made him a delightful and most genial friend and comrade.

It was in the thoroughly free life of the Adirondacks camp, to which through twenty years he looked forward with such pleasant longing from one summer to the next, that these qualities came most strongly to the front. No one could have entered with more zest than he into the rich informal pleasures of that enchanted spot. There reserve and formality could be laid aside and free play allowed to the instincts of hospitality and sociability and the playfulness of boyhood at its best.

Many friends came there as his guests, among them several colleagues, as Sir Michael Foster and Professor Waller, whose acquaintance he had made during an extended visit to England, and a number of companions of the pleasant Leipsig days — Brunton, Kronecker and Mosso, now no longer living. A ledge on one of the spurs of the giant mountain near the camp was dedicated to Mosso with amusing and mock stately ceremonies and still bears an inscription with his name. This compliment was delicately repaid by him later, through the dedication of a *Lago di Bowditch*, in Italy,[1] to his former host.

His widow, five daughters, two sons and ten grandchildren survive him. May his fine qualities live on in them and be transmitted to the generations yet to come!

## Miscellany.

### MEDICAL INSPECTION OF SCHOOLS IN MINNEAPOLIS.

In the issue of the Journal for March 2, we noted the recent resignation of Dr. Silas H. Ayer as chief school physician of Boston, and the comments made by him and others on the present condition of the medical inspection of school children in this city. In this connection it is of interest to consider some suggestions in a letter published on Feb. 27 in one of our daily papers:

"I have been reading with great interest the discussion in your news columns and editorial page in regard to the medical inspection in schools. I have seen no mention made of what, to my mind, is the key to the whole situation, that is, the fact that any properly co-ordinated system of school medical inspection should be absolutely and entirely under the control of the school committee. In no country in the world except our own is the medical inspection in schools under any other authority. In our own country the majority of cities have given the control of this inspection to the board of education, and the intent of the Massachusetts law was to throw it under the same authority as soon as possible.

"In New York, where the inspection is under the control of the board of health, the superintendent of schools in his report for 1907 says: 'Dual responsibility in the schools, that of the board of education and that of the department of health, always has resulted and always will result in confusion and inefficiency in the work effected. It is owing to this dual responsibility that the large annual appropriation made by the city for the physical examination of the school children is to a great degree wasted. Efficient service will be obtained only when the board of education is made solely responsible for all the work that goes on in the schools.' Superintendent Maxwell is still of the same opinion, and some of the principals of this city who recently interviewed a number of the inspectors in New York report that the inspectors themselves say that the work should be wholly under the control of the board of education.

"The board of health is primarily interested in the checking of contagious disease. Facts collected all over the country show the number of cases of contagious diseases, if we exclude pediculosis, amounts to only about 2% of the number of children. The work for the other 98% is primarily an educational matter, and so, for the matter of that, is the checking of contagious diseases in the schools. If Boston is at last

[1] In Italian Alps, "Cabana Margherita," near the high altitude observatory erected by Professor Mosso.

going to throw off the incubus of politically appointed school inspectors, the only way to accomplish that purpose definitely and finally is to take it out of the control of the mayor's office and his political satellites.

"CHARLES H. KEENE, A.B., M.D.,
*"Supervisor of Hygiene and Physical Training, Minneapolis Public Schools.*
"MINNEAPOLIS, Feb. 24."

Even though one may not agree with Dr. Keene's opinion, it is worth while, at a time when changes are likely to be made in our own method of medical inspection in schools, to consider the point of view of a supervisor in his position in one of our large cities.

## RESOLUTIONS ON THE DEATH OF DR. JAMES H. DENNY.

AT a recent meeting of the Boston Society of Psychiatry and Neurology, were adopted the following resolutions on the death of Dr. James H. Denny:

"By the death of James Henry Denny the Boston Society of Psychiatry and Neurology has lost an honorary member who was one of its founders and an active and faithful friend to the society in its earlier years. The members of the society mourn the loss of an earnest and diligent student, a high-minded gentleman and an unselfish and kindly friend."

(Signed) PHILIP COOMBS KNAPP.
HENRY R. STEDMAN.
WILLIAM N. BULLARD.

## SOCIETY NOTICE.

THE NORFOLK DISTRICT MEDICAL SOCIETY.—A regular meeting of the Society will be held at Masonic Temple, 171 Warren Street, Roxbury, Tuesday, March 28, at 8 o'clock. (Telephone, Roxbury 2275-3.) Business. Communications: "Hypersensitiveness to Serum or Anaphylaxis," Theobald Smith, M.D. Discussion by Edwin H. Place, M.D. Refreshments after the meeting. There will be no meeting in April. The Annual Business Meeting and Dinner of the Norfolk District Medical Society will be held Tuesday, May 9. The Censors will meet at Masonic Temple, Roxbury, Thursday, May 11, at 2 P.M., for the examination of candidates.

BRADFORD KENT, M.D., *Secretary*,
799 Blue Hill Ave., Dorchester.

## RECENT DEATH.

DR. WILLIAM WARREN POTTER, who died on March 14 at Buffalo, N. Y., was born in Strykersville, N. Y., on Dec. 31, 1838. He received the degree of M.D. from the Buffalo University Medical College in 1859, and immediately began the practice of medicine. In 1861 he was commissioned assistant surgeon of the Forty-Ninth New York Infantry, and served with his regiment throughout the Civil War, being mustered out with the brevet rank of lieutenant-colonel. Dr. Potter had been editor of the *Buffalo Medical Journal* since July, 1888, and was a member of many medical societies. He is survived by two daughters.

## Address.

### THE NURSE AND THE PUBLIC HEALTH.*

BY ANNIE W. GOODRICH, R.N.,
*Inspector of Training Schools of the State of New York.*

With honors that are accorded few men and fewer women, a few months ago England laid one of her daughters to rest. In the great Cathedral of St. Paul, a vast assembly knelt reverently as the Church gave thanks to God "that the sorrows and sufferings of his servant Florence were over." England lost a great patriot, the world lost a great humanitarian and a great teacher of sanitation and hygiene. And the shadow that always falls with the passing of a great soul was deepened for us in the United States, for only a short time before we had lost a disciple of Miss Nightingale, a great teacher and to some of us more than a teacher, a much-needed counselor and a dear friend. Death did not come to her gently at twilight, but in the full vigor of a splendid womanhood, with a suddenness and harshness to which it seems difficult to be reconciled; she was torn from the home she loved and the children who needed her, and hurled into eternity. At this very time there lay on her desk the opening lines of one further effort to present to the public the subject so near to both, — the Education of the Nurse. She was to have read this paper at the exercises in commemoration of the fiftieth anniversary of the founding of the first training school for nurses by Florence Nightingale.

The Crimean War and a grateful English public produced the systematized course of training for nurses that Miss Nightingale had already voiced the need of, "the essentials of which," she says, "may be shortly given thus:

(*a*) "That nurses should be technically trained in hospitals organized for the purpose.

(*b*) "That they should live in homes fit to form the moral lives and discipline."

How almost with bitterness she must have realized what such schools would have meant to her country when with her little band of forty nurses she faced that awful barracks hospital of Scutari, of which it is written that "when it had in it 2,400 patients, the rows of beds ought to have been 2¾ miles long, but so great was the overcrowding that the length must have been much less, perhaps only two miles long." They said it was her modest nature that made her shrink from the welcome of her appreciative countrymen and steal back unrecognized to Lea Hurst. I think it was not that; modest she was, but I think she could not face rejoicings and adulations with that terrible tragedy still haunting her — "Those lives, those lost lives," wrote Kinglake, in a burst of sorrow, "that timely care might have saved."

A great public health movement has recently swept over the country. A public aroused to the importance of the national health are investigating social evils that are producing crime and disease, that are depleting the population through infant mortality and limiting its efficiency through mental defectives.

And each investigating commission's verdict echoes Kinglake's cry, "The lives, the lost lives, that timely care might have saved," and what England needed then in time of great war, the whole world is asking for to-day in times of peace, — a body of trained workers to be the household guardians of the public health, teaching sanitation and hygiene in the homes, the schools and the institutions. To-day we have the training schools that Florence Nightingale hoped for, over 1,000, with 200,000 hospital beds and 29,000 pupils, but are not these 29,000 pupils trained for the individual need of the institution rather than for wider service of the state? A study of any group of institutions in the United States would bear this out. A recent comparison of the statistics of 125 hospitals shows the division of services to be approximately thus: 70% surgical, 20% medical and the remaining 10% to be divided between obstetrics and children, in favor of the former. A few have affiliated for obstetrics, and fewer still for pediatrics. A few have made some attempt at the preliminary course, by which we mean the essential theory with instruction in the simpler nursing procedures preparatory to the daily practice in the wards, a preparation that has long been deemed essential and struggled for by teachers of nursing and whose contention is sustained by our leading superintendents of hospitals recently studying in its broader aspects the education of the nurse. But so limited is the housing capacity, indeed, so often overcrowded is it, and so difficult is it to provide for the expense of needed additional supervisors and teachers, that I think but few institutions could establish such preparatory courses if they would. All this simply goes to prove that the hospitals are training the nurses for hospital work, and yet the greatest need of the country is for intelligent nursing in the homes. The hospital that trains the nurse in surgery is doing service for that hospital mainly and is doing a minimum service for the state. The same is true of the hospital that trains strictly in any specialty, whereas the state needs nurses trained and experienced in all phases of nursing.

On the other hand, we may ask in defense of this procedure of the hospital, Is it reasonable in these days of scientific advancement, requiring so much more thorough and comprehensive preparation of the nurse for public service, to lay this burden on private institutions? Certainly not beyond the point of equal service rendered. Is it reasonable for the state to expect a uniform result in any profession when the preparation of the members of such profession is left with each individual school, to be determined by whatever that school has to offer? It is not strange that a horizon dependent on a single point of view is somewhat narrowed, as the following anecdote, one of many, demonstrates: Contending recently for a broader training of the pupils in an institution whose service was almost wholly surgical, I was

* Delivered at the graduating exercises of the Training School of the Massachusetts General Hospital on Jan. 24, 1911.

told that the thorough training in surgical technic in an institution in which the equipment and administration was evidently above criticism more than prepared the nurse for all the medical work for which she would ever be called; that with our present excellent sanitary conditions, typhoid was a thing of the past; and I almost believed it, until, a week later, when in a town less than ten hours away, an inquiry as to the proportion of medical cases to surgical elicited the information that while the proportion was ordinarily 1 to 2 in favor of surgery, this year the former had been greater, owing to the epidemic of typhoid fever during the summer that had filled all of the medical beds and many of the private rooms. But if the institution cannot bear the burden of the broad education of the nurse, where shall we place it? Why not upon the state? Has the state that looks after its public schools, its teachers, its highways and its waterways, its fish and forestry, no responsibility in the preparation of its sanitary teachers? Could it not and should it not provide, if not in colleges, in the secondary schools, a preparatory course for those who would be nurses, courses that would be taken by every girl and woman who is wise. Miss Nightingale, preaching the Gospel of Prevention, said this fifty years ago:

"If the laws of health, as far as regards fresh air, cleanliness, light, etc., were taught to mothers and schoolmistresses (as well as nurses), would this not prevent some children being killed, some evil being perpetuated? On women we must depend, first and last, for personal and household hygiene — for preventing the race from degenerating inasfar as these things are concerned. Would not the true way of infusing the art of preserving its own health into the human race be to teach the female part of it in schools and hospitals, both by practical teaching and by simple experiments, inasfar as these illustrate what may be called the theory of it?"

And should the state not go still further and require that every institution maintaining a nurse training school with a three *years'* (note the emphasis) course shall provide, and that every nurse seeking to pursue her profession shall give evidence of having had, a definite experience under qualified teachers in properly equipped departments in the care of the child, in the care of the mother, in the care of the medical case as well as the surgical, in the care of the insane as well as the sane. Not any one would deny, I think, that maternity cases cared for in general wards do not provide proper experience in obstetrics; that a few sick children even in a separate ward supplemented by an extensive course of lectures is not a course in pediatrics. No one will deny that a complete and modern operating room, an active service, bare wards and aseptic furniture that prohibit the patients having little personal comforts, even the necessary toilet articles, without the properly constructed and equipped accessory departments, such as diet kitchens, pantries, etc., as important for the health restoring and safeguarding of the patients as the drugs or dressing, are not teaching fields, or rather they are teaching fields much to be deplored.

And if these limitations exist, as indeed they do, should not the state control, as it does in one country at least, and perhaps more, all institutions for the sick, making it necessary that evidence of sufficient funds to properly equip and maintain them shall be given, and wherever new institutions are being contemplated, requiring the submission of all hospital plans to a commission composed of hospital experts, one of whom shall be a nurse. I believe I am quite within the bounds of truth when I assert that thousands of dollars are spent yearly in trying to remedy, in recently constructed institutions, errors in construction and equipment that it is too late to ever wholly remedy, errors that the advice of such a board could not fail to avert.

And for our teachers, how are they prepared? If there are 1,000 schools of nursing, there are at least 3,000 qualified teachers needed in these schools alone. There are 566 district nursing associations with 1,400 workers, every one of whom to make her work of the far-reaching value in the community that it might be should have had some further preparation than just her training at the bedside of the sick. The Division of Child Hygiene of the Health Department in New York City alone, and there should be such a division in every city in the land, employs 143 nurses, of whose preparation the same thing could well be said, if the conclusions of the Bureau of Municipal Research, which I quote in part, are correct:

"The possibilities of such a division, progressively and efficiently administered, are beyond prophecy. A marked reduction in infant mortality, a higher level of health and vitality among children who live, and greater efficiency of the school system due to the increased ability of children to benefit by their instruction — not merely the application of remedies, but the discovery of the causes and methods of prevention of physical defects and low vitality; these direct results may reasonably be expected and demanded. More remote and less demonstrable results may be hoped for in the way of increased industrial efficiency, of correspondingly decreased poverty and dependency, and of decreased truancy and delinquency that now too often lead to wasted or even criminal lives."

I think I am correct in stating that there is just one college, not in the United States, but in the whole world, that offers courses for the nurse educator. The Teachers' College of Columbia University opened its doors to nurses in 1900 and since then little groups of women, the largest class we have ever had, the present, numbering 32, have entered to prepare themselves to be administrators and teachers in training schools for nurses. With no endowments, mainly supported by contributions from nurses and a few of their friends, this little sub-department, called the Course in Hospital Economics, has struggled on. The appointment by Dean Russell in 1904 of the most brilliant of our teachers to a chair in the college, which was made to include our little course,

established it more firmly, and last year a public-spirited citizen in New York, Mrs. Hartley Jenkins, through a large endowment, made possible at last what had been hoped for all these years — a Department of Nursing and Health. We rejoiced that Mrs. Jenkins' gift came before Mrs. Robb was taken from us. As Miss Nightingale's personal experience in the little school at Kaiserworth and in the hospitals of Paris confirmed her belief in the systematized course of training for nurses, so Mrs. Robb's actual experience as a teacher and as an organizer of two schools of nursing convinced her of the necessity, if the pupils were to be efficient and the organization effectual, of a definite preparation for the more advanced service of administration and teaching. Above all other departments of nursing, this was her child; from its inception to the day she died, she fought and worked and prayed for it. It was a teacher's bequest to her profession, and she could have no more fitting memorial than the scholarship fund that is being raised by the nurses throughout the country to make possible with so much less struggle and hardship the preparation of our women for the administrative and teaching positions that so badly need them. We would wish that the response to this tribute should come not only from nurses, but from every citizen interested in institutions for the sick and in the social welfare, and that every board of trustees would feel it possible to make a contribution that would insure the preparation of one or more of their graduates for executive work. We ask this, as Mrs. Robb did, for the public, not the nurse.

And now above all, what is our last and greatest need which cannot be met by endowments, and for which I fear there is no appeal to the state?

In an eloquent address in behalf of the Citizen Army Bill, for the home defense, Lord Roberts said "that every man should esteem it an honor to help in the defense of his country; every woman should feel that the children given to her are at the disposal of her country."

Our country needs her daughters, and I fear our mothers are withholding them. Would they say that the life of the nurse is a life of sacrifice, I would reply that the healthiest, happiest women I know are nurses. Would they say that they cannot submit their children to the severity of the preparation, I say to-day what those upon whom the doors of their alma mater are closing to-night will say to-morrow that "the happiest and most satisfying hours I have known in my whole life were spent in the wards of the hospital in which I took my training." If they would shield them from the knowledge of suffering and evil that such preparation involves, I would ask if any knowledge which will help the wonderful structure that God has given us as the container of his divine essence to better serve the state should be withheld from any man or woman.

There are diseases more devastating than any wars that might be prevented. There are eyes that are sightless that might have seen. There are clouded minds that call for the most skillful and intelligent ministration, that with such care might be restored to lives of usefulness and to a normal vision. There are poor diseased bodies that must labor but which might be helped to have the healthy bodies that make labor a joy, not a curse.

Once more, her call sounds in our ears:

"The Son of God goes forth to war.
Who follows in His train?"

"Oh, daughters of God, why are there so few of you to answer?"

To you who have this evening become my professional sisters, I extend an eager welcome. Our need of you is very great, and all the greater because of the richness of your opportunities. It has been your privilege to come in daily contact with some of the greatest minds of the medical world, to serve in an institution broad in its policies, thorough and comprehensive in its instruction, complete and modern in its equipment. You have been placed under a superintendent to whom no higher tribute could be paid than to say that she counted neither time nor cost in preparing herself to meet her great responsibilities; than to say to those of you who desire to prepare yourselves to serve in the institutions, as I earnestly hope some will, go and ask your superintendent not what you shall do, but what she *did*, and follow her example.

Your presence here to-night is evidence of the steadfastness of your purpose, of your fitness for the tasks that lie before you. The future is yours; go out, I beg, and demonstrate the highness of your calling and the value of your preparation. And if your trained eyes and hands and mind are but the servants of your heart, you cannot fail. Teachers you will be whether you will or no, whether the scope of your work is wide or limited; teachers whether by precept or by example. And who shall ever dare to estimate the value of, or limit the bounds of, the humblest example. Long after the textbooks that we have loved to teach from are replaced by ones more modern, the pupils of the training school will still bear the stamp of the splendid, joyful, living personality of their first head. The writings which alone should make their author immortal may lie untouched on dusty shelves, but the thousands of lamps lighted by the little lamp that broke the gloom of Scutari will never be extinguished. Remember that the greatest teacher that ever lived, before whom millions have bowed and said, "Master," wrote once only and that once in sand.

### FIBROUS STRICTURE OF THE RECTUM.*

BY JAMES P. TUTTLE, M.D., NEW YORK.

The title, "Fibrous Stricture of the Rectum," has been adopted to distinguish all other constrictions of this organ from those due to neoplasm, whether malignant or benign; therefore, we shall

*Read at a meeting of the Boston Medical Library in conjunction with the Suffolk District Medical Society, Dec. 21, 1910.

not refer to the latter condition, but confine ourselves to those which have no neoplastic characteristics. Stricture of the rectum is bound by no hard and fast rules as other conditions of this organ are; in fistula one may always say, Incise; in hemorrhoids, Clamp or tie; in cancer, Extirpate; but in stricture, the almost infinite variety of its causes, the changing physical characteristics and the various methods of treatment, depending upon these causes and the state of the parts, calls for exercise of greater judgment and experience than almost any other rectal condition. I use the term "condition" advisedly, for stricture in itself is not a disease, but the result of injury, irritation, ulceration or surgical interference, and must be studied and treated from its etiological point of view as well as from that of the physical or pathological conditions. In treating this subject, we shall adopt the modern anatomical divisions, as follows:

Anal canal — comprising that portion of the intestinal canal from the margin of the skin to the semilunar valves of Morgagni.

Rectum — from the free margin of the valves to a point about opposite the third sacral vertebra where the gut begins to be surrounded by peritoneum.

Pelvic colon or sigmoid flexure — comprising that part of the tract from about the third sacral vertebra, or beginning of the true mesosigmoid, to the lower end of the descending colon.

This division was first advocated by Treves and is not only anatomically correct, but "it gives to the organs definite limits; it separates the mobile from the immobile portions of the gut; it marks the line where the course of blood supply changes; it indicates the point where the three longitudinal muscular bands of the colon spread out and become more or less equally distributed about the gut; and, finally, it marks a point at which there is always a decided narrowing of the caliber indicating the juncture of the rectum and the pelvic colon."

The sigmoid, on the contrary, is a movable organ held only by the mesosigmoid and completely surrounded by peritoneum. It may be resected and the ends reunited by lateral or end-to-end anastomosis without the stricture recurring. The rectum, however, being surrounded by muscular and fibrous tissue in which inflammation and connective tissue deposits are prone to occur, cannot be excised or united end-to-end without an almost certain redevelopment of fibrous tissue and subsequently stricture at the point of reunion. The great dissimilarity of the pathological conditions found in the two organs renders it impossible to treat strictures in one upon the same lines as in the other, and we have, therefore, deemed it wise to confine our remarks strictly to conditions involving the anal canal and rectum.

The anal canal measures about 16 to 20 mm.; the rectum, 10 to 15 cm., somewhat less in women. All strictures of the rectum proper are, therefore, within the first six inches of the anal aperture.

## NATURE OF FIBROUS STRICTURE.

The nature of fibrous stricture, as has been well said by Mr. Cripps, "is to be regarded as the result of some irritation or inflammation affecting the parts." For many years it has been claimed that stricture of the rectum develops as an obscure deposit in the wall of the gut, due to constitutional disorders, chiefly syphilis, and unassociated with injury or pathological lesions. It was held that ulceration and destructive lesions of the mucous membrane were secondary to the stricture and that they were incurable without the removal of the stricture. Such a doctrine was advanced by Trelat and Forniere and led to a most unwise and ineffectual treatment of this condition. These views have in recent years been disavowed, and the profession now are practically unanimous in their belief that all strictures of the rectum, except the perirectal type, *have their origin in some previous intrarectal injury, irritation or ulceration.* As Mr. Cripps says, the causes of stricture are "first, the tendency of fibrous tissue, subject to inflammation, to become hypertrophied and contracted"; second, "the tendency of muscular fiber, when subject to undue and persistent nerve irritation, to undergo fibroid degeneration, with permanent atrophic contraction of its fibrous element."

The walls of the rectum are composed of four layers — the mucous, the submucous, the circular and the longitudinal muscular fibers. Outside of these the rectum is surrounded by the levator ani, the pelvic fascia, the perineal fascia and above by the peritoneum. The process of formation of stricture consists first in an inflammation or irritation in the organ, — this inflammation causes a destruction of the mucous and submucous tissues, — and, if the process ceases here, healing will occur without any material contraction of the organ; if, however, the process extends into the muscular layer, at whatever site, it increases the circulation and round-cell deposits, and when this has once been established it will follow the lines of the intermuscular fibrous bands which surround the rectum and will cause their hypertrophy, the compression, and subsequently the atrophy of the muscular fibers; the tendency of these fibrous bands to persistently contract will result in a narrowing of the caliber of the gut to a greater or less degree, according to the nature and extent of the inflammation.

This inflammation may be the result of ordinary infection or traumatism, surgical procedure, specific conditions such as syphilis, tuberculosis and dysentery. The process is the same in any case, although the pathological results may differ in detail, as will be referred to later on.

## MUSCULAR SPASM.

The influence of muscular spasm an an element in the production of stricture has long been a mooted point; some writers have claimed a pure spasmodic stricture, and I must say I have seen such strictures at the rectal-sigmoidal juncture; they are temporary, however, and, with patience,

they can be overcome, notwithstanding they may give the patient great inconvenience at times. A permanant spasmodic stricture is inconceivable, but shortening of the muscle and its accompanying fibrous bundles, due to frequent and prolonged spasm, may undoubtedly exist. Ball and Cripps lay great stress upon the spasm and contraction of the levator ani as a cause of rectal stricture, and cite it as parallel to the shortening of the ham string muscles in knee-joint diseases. I have never been able to convince myself that I have seen a positive demonstration of this type of stricture.

### CONGENITAL STRICTURES.

Besides these two causes of stricture, there is one other — congenital deformity — which has to be borne in mind. I say "deformity" because in the beginning these conditions are not true fibrous strictures, but the result of imperfect absorption between the layers of the epiblast and the hypoblast; there is practically no fibrous tissue at first but purely elastic tissue, which dilates and usually disappears upon a few dilatations if recognized early in life; if, however, they are unrecognized, the passages of fecal matter through the narrow caliber may set up an irritation and later on, in puberty or adult life, they may develop into true stricture, as I have seen in several cases.

### PERIRECTAL STRICTURES.

There is one type of stricture which can hardly be explained by the causes we have described above. A certain number of patients complain of rectal pain upon the passage of feces, whether hard or soft, upon walking or standing or upon an accumulation of masses in the rectum, yet careful examination of this organ shows no ulceration or local lesions to account for same. Digital examination does show, however, string-like, broad, annular or tubular contractions of the rectal wall, without any thickening of this organ and with the mucous membrane freely movable over the constriction. Such strictures are due to perirectal affections — they are usually post-operative or inflammatory disorders of women. The string-like strictures are occasioned by very fine adhesions or plastic bands in Douglas's cul-de-sac; they are never below two inches above the anus; are associated with many reflexes and almost always follow an attack of ovaritis or salpingitis, or pelvic peritonitis.

The broad annular strictures may be high or low; they are due to plastic deposits, adhesions of the broad ligaments or uterus across the rectum, or, as the writer has seen in two cases, practical obliteration of Douglas's cul-de-sac by adhesions of its walls and contraction around the rectum. This is not an infrequent result of complete hysterectomy and of superior pelvirectal abscesses. Neither of these types of stricture completely surround the rectum; they involve from one half to two thirds of the organ, are only sensitive anteriorly and laterally, and are not necessarily associated with any interior lesions of the rectum.

The tubular type of perirectal stricture, formerly considered always syphilitic, has been recently shown by Reynier and Quénu to be of undoubted tubercular origin, and usually if not always due to a tubercular deposit around the rectum.

Strictures are ordinarily divided according to their etiological factors and their physical characteristics; and it is difficult to say which is the more important, as one must consider them from both points of view in determining the proper line of treatment. The etiological factors in the production of fibrous strictures may be enumerated as traumatic, simple inflammatory, dysenteric, syphilitic and tubercular. Any condition which excites a chronic or destructive inflammation involving the muscular wall of the gut may be followed by a fibrous deposit and subsequent contraction, causing stricture. Operative or accidental traumatism of the walls of the rectum or anal canal may become infected and result in contraction of the rectal caliber, — a large majority of strictures which have come under my observation have been of this type. Most of these have followed operations for hemorrhoids, by improperly done Whiteheads, ligature and excision; two from clamp and cautery; a number from fistula; and twenty of greater or less degree from extirpations. In my own cases I have had very few post-operative strictures other than those following resection and extirpations. One of these was from a Whitehead operation in which my house surgeon, thinking there was too much oozing, removed the dressing and packed the rectum without introducing a proper speculum, — not wisely but too well, — for he tore the flap of mucous membrane that was sutured to the skin loose from its moorings and carried it up into the rectum ahead of his packing, thus turning the pumping vessel loose into the upper cavity and allowing the hemorrhage to continue. I was called after the patient was in a dangerous condition from shock — caught hold of the cuff that had been carried up into the rectum, brought it down and resutured it to the margin of the anus, after having stopped the hemorrhage. The result was imperfect union, a fibrous deposit and a very intractable stricture of the anal canal.

In over 4,000 cases of hemorrhoids operated upon by various methods, this is the only permanent stricture that has occurred in my practice from this procedure. McGavin, however, states that the clamp and cautery operation is the most fertile source of stricture that he has seen in his large experience. There must be some difference in the method in which this operation is performed here and abroad, else I would have seen it in my practice, as I use this method in 80% of my cases. I have seen three cases of stricture in which the clamp and cautery operation was said to have been done; in one of them I should say that amputation by the Paquelin had been employed, as two thirds of the external and internal sphincter had been removed, and there necessarily occurred cicatrical deposits at the site of this deep cauterization. After the ligature operation was said to

have been performed I have seen two strictures; and, after the so-called American method of Whitehead, I have seen five or more. Following resection of the rectum for carcinoma I have had five strictures of more or less caliber, in two of which there has been recurrence at the site of stricture; the others have been of a mild dilatable character and practically disappeared. In amputation there is always more or less cicatricial contraction at the juncture of the gut and skin at the margin of the anus; these do not always entirely disappear, and, although they sometimes cause a certain amount of inconvenience, the result, considering the gravity of the condition, has usually been considered quite satisfactory.

In the four cases in which I have seen pelvic abscesses open into the rectum, two have developed marked strictures above the site of the opening, and the other two to my great surprise, although they presented marked symptoms of stricture at the time of examination, have healed without any contraction of the rectal caliber. This brings up the point of temporary constriction of the rectum, due to large abscesses in the pelvic cavity, or to tumors of the broad ligament. As Mr. Cripps has pointed out, if one will place the finger in the rectum and at the same time pull upon the uterus and broad ligament, he will find a constriction of the rectum, showing a connection of the rectal fascia and fibrous bands with those of the pelvic fascia. When the tumor has been removed, or the abscess opened and the tension relieved, the stricture, if the inflammation has not invaded the rectal wall, will disappear. One cannot ignore this condition in examining for stricture. A number of cases reported in Mr. Cripps' work as stricture of the rectum have proved, on post-mortem examination, to have been pelvic or pelvirectal abscesses, which, had they been recognized and opened early in their history, would probably have never been fatal.

Simple proctitis or rectitis as a cause of stricture is difficult to discuss, for in this day of specific germs for every ulceration one hardly knows what to describe as simple. If, however, we assume that those destructive ulcers not associated with syphilis, tuberculosis or dysentery may be placed under this head, one may say that this is the most frequent cause of stricture because it is a part of every traumatic or post-operative stricture. The process by which it leads to stricture is described above, viz., infection, destructive ulceration, round-celled infiltration, fibrous deposit, muscular atrophy and persistent contraction.

### DYSENTERY.

There has been a long series of discussions with regard to the production of stricture by dysentery, but I shall not enter upon a pathological dissertation here. Those of us who have seen much amebic dysentery and the results thereof have seen strictures following this disease, although we have never been able to demonstrate the ameba in the stricture itself. The fact is that an amebic ulcer may become infected with colon bacilli, streptococcus, tubercle bacilli, etc., and these infections may produce a deeper destruction of the tissue than ordinary ameba, and then the stricture, while not dysenteric itself, will have had its origin in this disease.

### SYPHILIS.

Time would prevent my entering into an academic discussion concerning the influence of syphilis in the production of rectal stricture; besides, there is little new to be said on this subject. Outside of the presence of gummata, and certain changes in the blood vessel walls, there is practically no difference in the pathology of syphilitic stricture and those due to any other inflammatory cause; the process is identically the same, the destructive ulceration extending down into the muscular walls of the gut, the extension of the inflammatory process along the line of intermuscular fibrous bands, a crowding out of the muscles by hypertrophy and increased deposits of fibrous material, and the subsequent persistent contraction of these deposits, reducing the caliber of the gut and interfering with the return circulation in the veins: these compose the practical pathology of stricture, whether it be syphilitic, tubercular, or simply inflammatory.

To this interference with circulation I wish to call special attention! *It has been known for many years that the ulcerative process in this condition was chiefly below the stricture and not above, as has been stated by so many theorists, and said to be due to the friction caused by the passage of hard fecal matter. There is sometimes an erosion and irritation above the stricture, but this can be easily handled by dilatation and by keeping the fecal masses soft. Not so, however, with the ulceration below. All forms of treatment, whether local or constitutional, fail in the treatment of ulcers below the stricture except radical surgical procedure. The explanation of this lies in the fact that the contractile fibrous stricture limits the normal blood supply and obstructs the return flow through the superior hemorrhoidal veins to such an extent that there is an abnormal circulation in the part, — a deficient quantity of new blood and a stasis of what does go into the parts in the hemorrhoidal veins, thus preventing spontaneous healing or a normal response to local and constitutional measures.*

This explains why in syphilitic strictures constitutional remedies have practically no effect on the healing of these ulcers; it is not the obstinate syphilitic nature of the ulcer; the condition is the same whether the patient be syphilitic or not; the ulcers do not heal in either case until the obstruction to circulation be removed. It will thus be seen that practically syphilitic strictures differ very little from other strictures. It seems to me that stricture in the rectum of syphilitics varies from that in non-syphilitics just as ulceration in any other part of the body differs in syphilitics and non-syphilitics. In other words, the changes in the blood vessel walls, the increased round-celled infiltration, interfering more or less with the circulation in the parts, prevent response to ordinary medication. Constitutional medications may affect these con-

ditions, but they in no wise affect the fibrous tissue in the syphilitic any more than in the non-syphilitic. This condition once formed is not amenable to constitutional treatment.

### GONORRHEA.

Gonorrhea and chancroid have been enlarged upon by some authors as frequent causes of stricture of the rectum. As to the former, notwithstanding we have seen many more cases of this disease in our clinic during the last few years than formerly, we have not seen a single stricture of large or small caliber that we can attribute to it. Theoretically, if an ulceration from it should involve the muscular coat, there is no more reason why a stricture should not follow than from any other ulceration. As to chancre, these cases apparently do not come to my clinic, nor do I believe that they exist as frequently as in former years; at any rate, I have not seen those that extend high up into the rectum, or that were sufficiently destructive to cause a stricture of this organ.

### TUBERCULOSIS.

During the last few years tuberculosis has come to be recognized as a greater factor in rectal stricture than was formerly supposed. Many of the conditions that were once attributed to syphilis are now known to be tubercular. Modern methods of examination of the rectum have enabled us to recognize and diagnose as tubercular ulcerations that were formerly supposed to be syphilitic. It is true that the ulcerative process is not usually so deeply destructive in this disease as in syphilis, and consequently there is not such a large proportion of them that result in stricture because the muscular wall is not so frequently involved. I have published elsewhere my observations, both clinical and post mortem, on the frequency of tubercular strictures, or, as may be better stated, stricture following tubercular ulcerations. The stricture itself differs in no wise from those caused by other inflammatory conditions, except in certain cases we find miliary tubercular deposits on the surface, and sometimes following the minute blood vessels. There is another form in which it occurs, however, and that is in perirectal strictures, which I have mentioned above. This has been well described by Quénu and Reynier, and is, I believe, more frequent than even they have supposed. Personally I think I have seen it several times, but have failed to recognize it when seen. I remember two cases in the almshouse in which tubercular stricture existed without any ulceration in the mucous membrane and without the leathery feeling of ordinary fibrous strictures. There was a bosselated feeling to the rectum, with more or less congestion of the blood vessels, and a marked narrowing of the caliber. To the touch the condition resembled very much the early development of sarcoma, but the process failing to develop rapidly as in this disease, that diagnosis was abandoned. Under forced feeding, rest and mercurics the condition seemed to improve somewhat, but never disappeared entirely. This might lead one to believe that syphilis was present, but as we all know, and as has been recently brought to our view by the United States Army Medical Reports, this medicine has an influence upon certain tubercular processes, and as one of my patients died from pulmonary tuberculosis, I am confident that the condition in both of them was due to this process as there was never any evidence of syphilis elsewhere.

Recently I have had under my care a young woman in the Polyclinic Hospital in whom a stricture at the recto-sigmoidal juncture was found. My associates at first believed the same to be malignant; careful examination, however, revealed around the narrowed opening a verrucous tuberculosis. The abdomen was opened and the stricture was found to be due to an inflammatory deposit outside of the rectal wall and beneath the peritoneum; this deposit was dissected off and a No. 9 Wales bougie passed easily through the strictured area. Unfortunately for this poor girl, the tubercular process was found to extend throughout the colon and the cecum, and appendix was practically obliterated by tubercular deposits. Her physicial condition was not such as to justify the removal of the entire colon at that time, therefore I resorted to an ileo-rectostomy, hoping that by functional rest to her colon her health might improve to such an extent that we could remove the gut later. At that time she had a pulmonary tuberculosis which was quiescent; she improved for a while and her stools were reduced from twenty-five to three or four a day. Unfortunately, the long confinement in the hospital has caused the pulmonary condition to light up again and she is gradually failing on this account, while her intestinal condition is improved as much as one could expect. Here we have two types of stricture, one perirectal and one intra-intestinal, beyond all question tubercular. Much might be said of the pathology of strictures, but let us sum it up by saying that a large majority of strictures of the rectum are traumatic or simple inflammatory; that while syphilis does produce a certain number, they are much fewer than was formerly supposed; and, finally, that tuberculosis plays a much larger rôle in ulcerations and stricture of the rectum than was formerly supposed; and all of these factors must be taken into careful consideration when one comes to treat stricture of the rectum.

### PHYSICAL CHARACTERISTICS OF STRICTURE.

A second classification of stricture is based upon the physical characteristics; after this manner we may divide them into valvular, annular and tubular; and upon these types will depend almost absolutely the method of surgical procedure to be employed in their treatment.

### VALVULAR STRICTURE.

The membranous or valvular types are usually congenital and appear at the juncture of the rectum with the anal canal, or at the sites of

Houston's folds. They are chiefly composed of folds of mucous membrane, with a few fibrous and muscular bands; in early life they are soft and easily dilated, and, if properly treated in childhood, they disappear; if left, however, the irritation of straining and retained fecal matter cause infection and hypertrophy in the fibrous structure and subsequently a true fibrous constriction of the parts.

The true membranous or umbrella-like strictures occur at the junction of the rectum with the proctodaeum and are due to the imperfect absorption of the layers of epiblast and hypoblast. Incomplete dilatation of simple imperforated ani are frequently its cause.

As to the valvular type, this condition is not recognized as a true stricture; they are normal structures, but they may be deformed and obstructive, thus causing irritation and inflammation and fibrous deposits which shorten the free edges of the mucous folds, forming pockets similar to the cups in a grain elevator; such pockets catch and retain fecal material, often causing autotoxemia, rectal discomfort and even ulceration which may produce true fibrous stricture. It is this type of rectal deformity upon which Martin has based his theory of valvular obstruction and its influence in the production of constipation. The condition is not nearly so frequent as it was formerly believed to be, but it does exist and its proper treatment gives most gratifying results.

### ANNULAR STRICTURE.

This type of stricture is usually due to traumatism, simple ulceration, tuberculosis or dysentery; it begins abruptly and usually surrounds the entire rectum; it is movable when the patient is squatting or in a semi-prone position; there is a sulcus around it into which a probe or bougie is much more liable to pass than into the caliber of the stricture; there is always mucous discharge, ulceration and secretions which are less than in tubular strictures. It is this type of stricture that follows acute or tubercular ulceration of the rectum chiefly.

### TUBULAR STRICTURE.

This type of stricture follows chronic inflammatory conditions, whether simple, tubercular or syphilitic; it involves from three fourths of an inch to six or more inches; it begins gradually in a cone-like contraction; it has no sulcus around its aperture, it is immovable and accompanied by much discharge — dark and feculent in syphilitics; and creamy white and purulent in tuberculars. Its chief symptoms are diarrhea, or rather frequent calls to stool, with a discharge of mucus, pus and blood; there is difficulty in obtaining a satisfactory stool, especially if the fecal matter is hard; incontinence and constant discharges if the stricture is low; aching pain around the pelvis; loss of flesh; reflex digestive disturbances; and shooting pains in the pelvis and urinary organs.

Upon these physical characteristics will depend largely the method of surgical treatment regardless of its pathological nature.

### DIAGNOSIS.

Diagnosis of the existence of stricture within the limits which we have set — the lower six inches of the intestinal tract — is a simple matter. It can either be felt with the finger or seen through a pneumatic proctoscope; its extent, dimensions, caliber and the complications surrounding it are rather more difficult. The subjective symptoms, such as constipation, diarrhea, incontinence, discharges, reflexes, etc., are familiar to you all. Digital examination is the chief factor and practically without danger if one is only careful not to use great force. The fatty degeneration and friable condition of the rectal walls render this liable to rupture, and that rupture will always be in the line of least resistence — toward the peritoneal cavity. So far as rectal bougies are concerned, I have long since ceased to look upon them as instruments for diagnosis; they are so liable to lodge in the sulci beneath the stricture or be grasped by the sphincter muscle so that, if by chance they enter the aperture of the stricture, one cannot tell whether they are held by the stricture or by the muscle. So many instances of perforation or rupture of the gut have followed their use that I consider them too dangerous to be employed in this condition by even the most expert.

Whenever the stricture is above the reach of the finger, its existence may be found by a proctoscope introduced up to the constriction, and one may see clearly the aperture and the diseased area. In order to determine the caliber and extent of the stricture, one may employ an olive bougie, exercising the least possible force, or a probe fashioned after the manner of Martin, with which one can tell by palpation when he has passed beyond the diseased area and comes upon smooth mucous membrane. It is true that this requires a high degree of sensitive education, but it is the most practical way to determine the extent of the disease without any danger to the patient. This difficult diagnosis is not often necessary, as a large majority of strictures are within reach of the finger and can be easily made out.

The methods of examination; characteristics distinguishing tubercular, syphilitic and simple ulcerative processes associated with stricture; differentiation between malignant and non-malignant obstructions of the bowel have all been fully described in my work on "Diseases of the Anus, Rectum, and Pelvic Colon" and need not be repeated here.

### TREATMENT.

It will be seen from the foregoing that treatment of stricture does not merely consist of widening or removing the stricture; it also involves the treatment of etiological factors as well. It were better to leave the condition alone than to attempt to dilate forcibly or extirpate in the face of a

large quantity of pus and infection. There are two radical cures for stricture: First, preventive; second, amputation, but we cannot always apply these methods. The average case comes into the hands of the specialist usually after true fibrous stricture has been established, and thus prevention is impossible. If the general practitioner would attach more importance to local examination and add more emphasis to the necessity of this in dealing with patients where there are symptoms indicating disorders of the rectum, I am confident that stricture would be reduced more than 75% of its present frequency.

Most ulcerations of the rectum, if diagnosed early, could be checked in the destructive process and healed before they involve the muscular walls of the intestine. I cannot go into the details of such treatment, but if I can impress upon you the necessity of local examination in all cases of diarrhea and constipation, in cases of tuberculosis or syphilis, whether they present rectal symptoms or not, my mission here will have been accomplished. I attribute the infrequency of post-operative strictures at my clinic to the fact that we are in the habit of using a large-sized Lynch tube after most operations for hemorrhoids, stricture and amputations, and we invariably begin to dilate with our fingers on the fifth day after operation, thus stretching the new fibrous deposit, increasing the flow of blood to the parts, inducing absorption of plastic material and at the same time stimulating muscular contraction in the circular fibers, causing them to resist the encroachment of fibrous deposits and keeping them alive, as it were, to their function of contraction and relaxation.

Most of the strictures which we have following resection have come in cases that have lived away from New York, and in whom the dilatation has been trusted in other hands. I do not mean by this to offer any criticism on my good friends who have done the best they know, nor do I say these would not have occurred had I treated them myself, for I believe there is such a tendency to this result that I have practically discontinued the operation in the rectum itself. But I do believe that most all post-operative strictures could be prevented by proper after-treatment.

### DILATATION.

Gradual dilatation is a part in the method of treatment for all strictures. In the early stages, when the fibrous material is soft and elastic, I have no doubt that by this method many strictures can be dissipated; the idea, however, that it can be done by a bougie is based upon a false conception of the parts. A normal anal canal measures about 3 cm. in circumference; above this the rectum dilates very rapidly, and in its normal condition measures 5–15 cm.; therefore, it would be impossible to introduce through the anal canal any instrument that would at all fill up the rectal ampulla. How, then, can one expect to dilate strictures of the rectum, except those with very narrow calibers, by an instrument that can be introduced through the anus. In the early stages of stricture, when they are of large caliber, a bougie is useless to dilate. One would naturally turn to a Barnes bag, or a Robert's dilator, which, being introduced into the caliber of the stricture, may be blown up and stretch the constriction. Theoretically this is ideal, but having had the experience of rupturing one intestine and almost killing my patient with one of these instruments, and having heard of two others, I have not the temerity to use or the boldness to recommend them.

The friable condition of the gut wall at a point below and above the stricture, and the impossibility of knowing how much force is being exercised by pneumatic or hydraulic pressure, renders these procedures very dangerous. Where the stricture is within the reach of the finger a long Humphrie's speculum or flat retractor may be introduced through it and the finger used to dilate and massage the stricture with good effect and is far safer than any concealed instrument or bougie of whatever type. If the stricture is above the reach of the finger and is of wide caliber one may introduce a proctoscope and through it dilate and massage by long forceps or probes, or, he may without great danger introduce a Wales bougie with the flanges removed and which does not fit too tight; this being left in the stricture will gradually dilate it so as to decrease the discomfort of the patient, but such a process will never cure a well-developed stricture.

Rapid dilatation or divulsion in stricture of the rectum is absolutely unjustified. Rupture will always take place in the line of the least resistance and this line is almost always toward the peritoneal cavity.

### PROCTOTOMY.

The operation of proctotomy consists in incising the rectum; in stricture it may be partial or internal and complete. Partial proctotomy has been condemned by most rectal surgeons on the ground of danger from hemorrhage and infection; in my own experience, however, I have obtained some very good results from this operation, especially in annular stricture. I do not employ the knife, however, in making the incision; I use an electric cautery blade and always employ it through the proctoscope. The incision is made posteriorly and always a little to the left of the median line in order to avoid the usual site of the superior hemorrhoidal artery. This burned incision closes up all lymphatics and blood vessels, thus avoiding absorption, infection and hemorrhage. The operation is not employed in strictures less than two and a half inches from the anus, for I consider complete proctotomy or amputation better adapted to those within range.

### COMPLETE PROCTOTOMY.

This operation consists in incising the rectal wall through the stricture from a point about one half an inch above the latter out to the tip of the coccyx, involving both sphincters and extending back to the bone throughout its length. While I have yet to see a case of true fibrous stricture

cured by this operation, I still believe it is one of the most beneficent in rectal surgery; it relieves the obstruction, loosens up the contractions, thus removing to a certain extent the interference with circulation below the stricture; it gives full drainage and is in itself practically without any great danger. Sometimes it is followed by infection and abscesses in the cellular spaces and requires prolonged after-treatment and practically a bondage to the bougie for the rest of life. At the same time, it can be done by any one and when radically performed at the psychological moment has saved many lives. Theoretically one would say that the bowels should be emptied and suppuration controlled before such an operation; practically this is impossible, as it must be done at times upon the spur of the moment and one marvels at the few fatalities which follow such an operation under such conditions. In long tubular strictures, the upper end of which cannot be determined, and where there is no great emergency, the operation should not be performed, but should be substituted by colostomy, which is our sheet anchor in the preparation of such patients for the radical cure or for a life of comparative comfort with the stricture left unattacked.

After complete proctotomy has been performed, complete dilatation is necessary until the ulceration is entirely healed; this is ordinarily accomplished by the use of a large bougie or digital dilation. The danger of the bougie consists in the fact that if the anal canal is kept widely enough dilated in order to introduce an instrument large enough to stretch the rectal canal, the former may become so enlarged as to cause incontinence. It seems, therefore, that some instrument, such as Barnes' bag, Hirschmann's or Roberts' pneumatic dilator would be applicable in cases like this. I am of the opinion that, having cut the fibrous and restraining tissues of the stricture thoroughly, these instruments would not be so dangerous as I have described above, for the line of least resistance would then be in the line of incision, and rupture into the peritoneal cavity would not be so imminent; one should be very careful in their use and in the amount of force exerted.

### EXTIRPATION.

Since my last public utterance upon this subject in 1903 (Diseases of the Anus, Rectum and Pelvic Colon), in which I advised in a conservative way the local resection of the strictured area and an end-to-end union, my experience with this method has been considerable. Up to 1909 I had not lost a case either by the sacral, perineal or combined methods of operation in non-malignant strictures. Since then I have lost two — one through shock following a combined operation, and the other following a perineal operation six months later, which I shall describe further on. These two cases make my mortality about 6%. The results of resection, however, have been altogether unsatisfactory; with the exception of four cases there has been more or less recurrence, usually more, and in every case at the site of the end-to-end union. This experience and the fact that a large number of strictures are limited to the lower four inches of the intestinal tract have led me to adopt the method of complete extirpation or amputation in all cases in which this operation is feasible. Every year adds to my confidence in the perineal method; as one becomes more and more familiar in its use, its possibilities and the amount of gut that can be brought down and sutured to the anus without abdominal section is demonstrated. In two cases recently I have taken out 12½ and 11½ inches of the bowel by measurement and have been able to bring the gut down and suture it to the margin of the anus without any tension whatever. Although we have not had perfect primary union, the results have been satisfactory in that the patients have recovered with very little incontinence and none of them have been confined to the hospital longer than four weeks.

The technic of this operation is described in my work already referred to and need not be repeated here. The operation is limited, however, to finding the gut in a proper condition for such a procedure; where there is an extensive ulceration invading the perirectal tissues, or accompanied by complications such as rectovaginal, rectourethral or perineal fistula, one is hardly justified in attempting such radical operative interference, as infection will probably take place, and if it involves the peritoneum, a fatal issue is most likely to occur. Under such circumstances one should delay the radical operation until these conditions can be cleared up. There is also another condition which renders this operation dangerous, and that should be carefully considered before one undertakes it; this is a fatty degeneration of the gut wall, found in old syphilitic cases, and sometimes extending throughout the area of the sigmoid, if not the colon itself. It is always necessary in this operation to exert a certain amount of force in traction upon the gut during the procedure, and where this degeneration of the walls is present, the intestine is liable to be torn across and infection of the parts occur.

This was the eventual cause of death in one of the cases mentioned above. This patient had an old syphilitic stricture of the rectum, with extensive ulcerations below and a rectovaginal fistula. It was not deemed wise in her case to attempt radical operation at once on account of these conditions. A temporary colostomy was made in the transverse colon in order to turn the fecal current aside and give the ulcerations below an opportunity to heal. This being done, everything proceeded encouragingly, the ulceration disappeared, the stricture itself softened and everything seemed favorable for amputation of the strictured area. At the time of the first operation thickening of the walls of the sigmoid and enlargement of the appendices epiploicæ were observed. The woman had undergone forced specific treatment, and we believed that this condition would have improved as well as that in the lower end of the gut, and we undertook the amputation with great confidence. Having dis-

sected out the cicatrical tissue and loosened the gut up to Douglas's cul-de-sac, we proceeded to bring it down. To the touch it did not seem to be much thickened or inflamed; while I was loosening the mesosigmoid, one of my associates was making traction upon the gut; how hard he was dragging I cannot say, but as I snipped the last fold of the peritoneal band holding the gut, it came down with a jerk and was torn across at about a level of the sacral promontory, some five inches above the stricture and far above the point at which I had hoped to attach it to the margin of the anus. It was now impossible to think of bringing this torn end down; therefore, I grasped it with my hands and clasped it across with a strong clamp; I then packed the parts off with gauze, leaving a drainage at its end, and as the woman was in a state of shock, discontinued further operation, thinking that I would have a perineal fistula and would have to leave the woman with her artificial anus permanent. In four weeks she left the hospital in good condition, although greatly disappointed. Shortly afterwards she developed an acute pneumonia for which she was brought back to the hospital and recovered. After this there developed a large abscess in her abdomen which was opened and which was clearly shown to be connected with the lower end of the sigmoid which had been torn off; this was determined by the fact that irrigation through the distal opening of the artificial anus flowed out through the abscess cavity, notwithstanding the fact that the spur of the artificial anus worked and there was no escape of fecal matter in this direction. She shortly afterwards began to pass liquid feces through the abscess cavity and rapidly failed. Autopsy showed a rupture into the abscess cavity from the ileum about eight inches above the cecum. Such an accident will, of course, be rare, but it is worth while to keep this condition in mind, and in these old syphilitic cases either be content with a good artificial anus, or to wait a long time before attempting a radical operation.

Time would prevent my describing the operation of Bacon, the recto-colostomy of Kelly and other methods of operation for stricture of the rectum which are applicable only in very limited and high strictures; we cannot close, however, without considering one of the most beneficent means of treating this condition, viz., colostomy.

This operation is to be looked upon in three lights: *palliative*, *preliminary* to radical operation, and *curative*. Where the stricture is long and tubular and accompanied by ulceration and discharge or complicated by fistula and large abscess cavities, colostomy is undoubtedly one of the most beneficent operations in the whole field of surgery. It affords ample egress for the fecal matter, it protects the diseased area from acrid discharges, it relieves most of the reflex digestive disturbances, enables the patient to be built up by proper feeding and provides the best possible condition for the treatment of ulcers and strictures locally. Where the patient is unwilling to submit to this as a permanent condition, the operation may be held out as preparatory to radical extirpation, and it certainly is most useful in this procedure.

As a curative method, I am not able to point out many cases in which it has been successful; there is no question, however, that in almost every instance in which it has been done there has been a radical recession in the ulcerative process, and in many cases the stricture has been found to soften and become more easily dilated, and in some cases seemed to disappear entirely. In one case, which I have reported elsewhere, this process seemed so perfect that I closed the artificial anus believing that the patient was well; after about a year she returned to the hospital and I found that the stricture had recurred and was as tightly contracted as ever so that the artificial anus had to be restored, and, so far as I know, the patient carried it through life.

In one instance in which the stricture extended from two inches above the anus well up into the sigmoid, the woman had been brought into the hospital for carcinoma with obstruction of the bowel. A rapid colostomy was made and her symptoms relieved. In this case there was never any absorption of the stricture, the fibrous process and its tendency to contract continued through life, and the last time that I saw her it was with difficulty that I was able to pass a No. 10 French urethral bougie through the rectum and into the lower end of the artificial anus. This minute opening was kept up for ten years in order to prevent an accumulation of the intestinal secretions above, but the patient learned to manage the anus so perfectly that she was never willing to have the radical operation done, nor was I willing to advise it. She lived fifteen years after the operation and was the most grateful patient I have ever had; she died of a broken neck, having fallen down stairs one morning when going to her kitchen.

The important question with regard to colostomy in these cases is whether the aperture is to be permanent or temporary. In long tubular strictures, and those with severe complications, as have been mentioned above, I believe it is desirable to convert these patients to an acceptance of a permanent artificial anus; the dangers of operation and the uncertainty of continence after it renders it probable that they will be quite as comfortable with the opening in the side as after a radical extirpation. If, then, one believes that radical extirpation is going to be improbable, it would be better to make for them at once a modified Bailey colostomy, and thus end the matter. If, however, there are reasons to believe that one can extirpate the stricture and restore the fecal exit to its normal site, then I believe we should make the colostomy in the transverse colon, above the umbilicus, for the following reasons: First, There is never any danger but that the mesocolon will allow a perfect spur and hence no leakage into the gut below. Second, There is less liability to prolapse because the force of gravitation will drag the gut down instead

of forcing it out through the aperture. Third, and chiefly, because it does not interfere with the dragging down of the sigmoid to any extent that may be necessary in the radical operation to be done.

## HEMORRHAGIC DISEASE OF THE NEWBORN.*

BY ROBERT M. GREEN, M.D., BOSTON, AND JOHN B. SWIFT, JR., M.D., BOSTON.

(From the Clinic of the Boston Lying-In Hospital.)

The subject of hemorrhagic disease in the newborn is one of peculiar interest, not only because its etiology is still uncertain, but because it is one of the serious emergencies of early infantile life, in the treatment of which important progress has been made in recent years. The disease was first described as a clinical entity in 1852 by Dr. Francis Minot,[1] of Boston. In 1891, Dr. Charles W. Townsend,[2] of Boston, published a valuable paper reviewing the literature of the subject since Minot's time and reporting a series of 32 cases from the clinic of the Boston Lying-In Hospital, together with 577 cases collected from other writers. From an analysis of these cases he reached the conclusions that the disease is probably due to an acute infection, that its mortality in all forms is about 75% and that its treatment is best directed towards mechanical control of the hemorrhage and maintenance of the strength of the patient.† Taking Dr. Townsend's original paper as a point of departure, it is our desire to report a further series of 51 cases from the clinic of the Boston Lying-In Hospital, and to discuss briefly the bearing of their statistics on the etiology and on the various methods of treatment of this disease which have been advanced during the past twenty years. For the privilege of consulting the records of the hospital and of observing some of the cases in the wards, we wish gratefully to acknowledge our indebtedness to the courtesy of the visiting physician and other members of the Boston Lying-In Hospital staff.

The 51 cases which form the basis of this paper occurred in the wards of the hospital from June 19, 1904, to April 1, 1910, a period of nearly six years. The total number of babies born in the hospital during this time was 4,455, showing a percentage incidence of 1.14% as against 0.57% in Dr. Townsend's series. We have presented these cases in tabular form, noting particularly the parity and the civil condition of the mother, the duration of labor, the fetal position and the complications of labor and puerperium, the date of delivery, the age of baby at onset of disease, the treatment and the result. We will next proceed to an analysis of these cases to determine the bearing, if any, of each of these factors on the problems of the disease.

Of the 51 mothers, 31 were primiparæ, 20 were multiparæ. It has been thought that firstborn children are more subject to the disease than those of subsequent pregnancies, chiefly because of the longer average period of labor to which they are subjected. The present figures would seem to bear out this assertion, but in reality we believe they do not, since this proportion is approximately the same as that of primiparæ to multiparæ in the entire clinic. In none of the multiparæ of this series is there any record of hemorrhage in previous children. This fact would tend to controvert the theory that the disease is analogous to hemophilia, or in any way dependent on a hereditary dyscrasia.

Thirteen of the 51 mothers were single, 38 were married. This again would seem to bear out the supposition that illegitimate children are more subject to the disease; but again this is approximately the proportion of illegitimacy in the entire clinic.

The presentation of the fetus in every case was a vertex, but any series of 51 cases taken at random might well fail to include any other variety.

As stated above, it has been held that length of labor is an important predisposing factor in the production of the disease, from the exhaustion to which it subjects the fetus. The present statistics, however, would not seem to bear out this supposition. The longest labor of the series, it is true, ran to seventy hours, but this baby recovered, and of the 25 who died, 10 were born after less than twelve hours of labor. The average duration of labor for the entire series is fourteen hours thirty-seven minutes, which is only slightly above the general average for a large number of unselected cases.

Nine of the labors were forceps deliveries, again about the same percentage as of all cases in the clinic. One of the mothers had pneumonia at the time of delivery, one had mitral regurgitation, and one impending eclampsia. One mother was an epileptic. Three of the puerperia were complicated by slight uterine sepsis, two by mastitis, one by salpingitis, and one by scarlet fever. It does not seem that any of these complications or attendant circumstances could have had any bearing on the hemorrhagic condition.

The seasonal distribution of the cases seems, on the other hand, distinctly significant. Of the 51 cases, 39 occurred during the six months from November to April inclusive, and only 12 during the six months from May to October inclusive. This proportion, which is essentially the same as that of the seasonal incidence of such infections as impetigo, diphtheria and bronchopneumonia, should confirm the theory of the infectious etiology of the disease, which is more prevalent during the months when ventilation is poorest and general resistance to infection is lowered.

Again it is instructive to observe that 33 of the cases occurred in distinct groups, after the manner of hospital infections. These groups are indicated in the table by brackets, including such cases as occurred closely enough together to admit of being due to a common infection. Of these groups, the most remarkable, and the only one amounting to a distinct epidemic, is the next to the last, of 13 cases, when from Dec. 20 to the following

* Read before the Surgical Fortnightly Club, Boston, Feb. 21, 1911.
† In a subsequent paper[3] Dr. Townsend reported 18 additional cases; but we have confined ourselves to the first series for comparison.

## Table of Cases.

| No. | Hospital record. | Mother. Parity. | Mother. Status. | Labor. Position. | Labor. Duration. H. | Labor. Duration. M. | Complications of labor or puerperium. | Date of delivery. | Age at onset. Days. | Location of hemorrhage. | Treatment. | Result. |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 1 | 118–78 | 1 | M. | O.L.A. | 12 | 50 | | June 19, 1904. | 2 | Tarry stool. Purpura right leg. | | |
| 2 | 119–192 | 1 | M. | O.D.A. | 6 | 25 | | Sept. 21, 1904. | 4 | Two rectal hemorrhages. | Brandy. Modified milk. | Well. |
| 3 | 119–194 | 9 | M. | O.L.A. | 11 | 50 | | Sept. 22, 1904. | 3 | Hemorrhage from mouth and rectum. | Brandy. Gelatine 2% ev. ½ hr. p.o. Salt solution with gelatine p. r. ev. 6 hr. | Well. |

March 20, there was not a single day when there was not in the hospital a baby who had, or had had, hemorrhagic disease.

The average age at onset for the entire series was three and one-half days. The average age at onset for the fatal cases was only slightly less, three and one-fifth days. The only two cases that began after the tenth day both recovered. The greatest age at onset among the fatal cases was nine days, but all the other fatal cases occurred under seven days. This would seem to indicate that after ten days the disease is infrequent and the prognosis good; that after a week, the prognosis is fairly good; but that under a week the prognosis is poor and the age at onset has no particular bearing on the prognosis.

The subject of the location of the hemorrhages raises at once the question of classification of types of the disease. Townsend tabulated his cases according to the source of the hemorrhage, and for the sake of comparison we have placed ours in a similar parallel table with his. It does not seem, however, that this method affords important information. Clinically the cases arrange themselves in three distinct groups as follows: First, those in which the hemorrhage is principally from the umbilicus; second, those in which it is principally from the mucous or serous membranes; third, those characterized principally by the formation of subcutaneous purpuric patches or ecchymoses. These types we have designated respectively the umbilical, the sero-mucous and the purpuric, according to which form of hemorrhage predominates. The important bearing of this classification is on prognosis. Grouped in this manner, the cases and their results in our series may be presented in the following table:

Comparative Tables of Sources of Bleeding in Hemorrhagic Cases.

| Sources. | Townsend's series. | Green and Swift's series. | Total. |
|---|---|---|---|
| Intestine, | 12 | 23 | 35 |
| Stomach, | 12 | 7 | 19 |
| Mouth, | 12 | 9 | 21 |
| Nose, | 8 | 7 | 15 |
| Navel, | 14 | 15 | 29 |
| Ecchymoses of skin, | 11 | 14 | 25 |
| Crack of skin, | 1 | 2 | 3 |
| All of above sources, | 3 | 0 | 3 |
| Meninges, | 0 | 2 | 2 |
| Genito-urinary tract, | 0 | 3 | 3 |
| Eyes, | 0 | 1 | 1 |
| Navel alone, | 2 | 6 | 8 |
| Gastro-intestinal tract alone, | 15 | 2 | 17 |
| Stomach, mouth and nose alone, | 7 | 2 | 9 |
| Intestines alone, | 3 | 9 | 12 |
| Ecchymoses alone, | 2 | 1 | 3 |

Classification of Hemorrhagic Cases.

| Clinical type. | Recoveries. | Deaths. | Total. |
|---|---|---|---|
| Umbilical, | 6 | 9 | 15 |
| Sero-mucous, | 13 | 14 | 27 |
| Purpuric, | 7 | 2 | 9 |
| | 26 | 25 | 51 |

It would appear from this that the mortality of the umbilical type is about 60%, that of the sero-mucous type about 50%, and that of the purpuric type about 22%. It remains to consider the various methods of treatment employed and the results obtained from each.

The treatment of hemorrhagic disease may be local or general or both. When possible, its aim is to check the actual hemorrhage and to prevent its recurrence by such measures as may increase the coagulability of the blood. The local agents employed are the same as those used to check hemorrhage under other conditions. Compression, adrenalin chloride and other astringents have been used, and sometimes seem of value in minimizing the amount of bleeding. In general, however, these agents are often as unsatisfactory as in other conditions. When the bleeding is from the gastro-intestinal tract, local application is impracticable, and the administration of paregoric to allay peristalsis seems to have little effect on bleeding. Attempts to check umbilical hemorrhage by pursestring suture are inadvisable, as the bleeding continues from the stitch-holes.

The general treatment of hemorrhagic disease may be grouped under three headings: First, the use of gelatine and calcium salts; second, the use of animal sera; third, the use of direct blood transfusion. It is instructive to consider these methods of treatment historically and with reference to results obtained.

At the time Dr. Townsend's paper was written, the treatment of hemorrhagic disease was essentially limited to local styptics and general supportive measures. Not long afterwards, the use of gelatine by mouth and rectum was advocated in hemophilia and cholemic hemorrhage, and was adopted in hemorrhagic disease of the newborn apparently with beneficial results. Dr. Townsend was enthusiastic in its use, and subsequently reported [4] a case in which it seemed of advantage. When the effect of Ca salts on the coagulability of the blood was discovered, these also were employed in hemorrhagic disease. Until 1908 these measures constituted the routine treatment of the disease.

In 1908, however, Leary's experiments with normal rabbit serum suggested its employment in this condition, and accordingly its use was begun at the Boston Lying-In Hospital. It was given subcutaneously in 30 ccm. doses, repeated two or three times, in case the bleeding recurred after the first dose. Opinions differ as to the value of this treatment. Its numerical results are indicated by the accompanying table.

Table of Methods of Treatment and Results.

| Treatment. | Recoveries. | Deaths. | Total. |
|---|---|---|---|
| General supportive, | 2 | 4 | 6 |
| Local hemostatic, | 2 | 5 | 7 |
| Gelatine, | 9 | 4 | 13 |
| Rabbit serum, | 12 | 10 | 22 |
| None, | 1 | 2 | 3 |
| | 26 | 25 | 51 |

Finally, Crile's experiments in direct blood transfusion suggested its use also in hemorrhagic disease, and it was employed in one case (No. 36) of this series, after a dose of rabbit serum had

failed to arrest bleeding. The transfusion was successful, but the patient died. This single case is, of course, inconclusive as to the therapeutic merits of this procedure. It has been followed by recovery in several cases, and in a recent article[5] Lespinasse and Fisher report its use in six collected cases with four recoveries, and speak enthusiastically in its favor as the ideal treatment. Without admitting this contention as proved, it seems that the method certainly deserves careful and extensive trial.

In the interpretation of the present series of cases there are to be taken into account several considerations which prevent its results from being conclusive or its percentages reliable indications, except in a general way. In the first place, there is some latitude of diagnosis; probably several cases included in the series were not really, and would not formerly have been considered, hemorrhagic disease. Second, the cases may be of various types and of varying degrees of severity, so that the apparent efficiency or inefficiency of any one method of treatment may depend not on its own merits, but on the type and severity of the cases treated by it. Third, in many cases several methods of treatment have been employed, so that in these cases neither recovery nor death can accurately be attributed to any one remedy.

Though all indications point to the probable infectious etiology of this disease, we believe that further study should be made of the microscopic blood picture in this condition, especially with reference to the platelet count. Research on this subject has already been undertaken by Dr. Swift, and its results will be presented in a later paper.

### CONCLUSIONS.

1. The parity and civil status of the mother, the fetal presentation, the duration of labor and the complications of labor and the puerperium are factors of no significance as predisposing or determining causes of hemorrhagic disease in the newborn.

2. The seasonal incidence and the occurrence of hospital cases in groups tend strongly to confirm the theory of the infectious etiology of the disease.

3. The earlier the onset of the disease, the worse its prognosis; after one week, the prognosis becomes relatively, and after ten days, absolutely, good.

4. Clinically the disease occurs in three fairly distinct types, the umbilical, the sero-mucous, and the purpuric, which have an approximate respective mortality of 60%, 50% and 22%. The gross total mortality is about 50%.

5. The treatment should be directed toward local hemostasis and increase of coagulability of the blood. Gelatine and rabbit serum are agents of proved value. Quiet and isolation are indicated in every case. Blood transfusion is a promising procedure which deserves further trial. The ideal treatment has not yet been demonstrated.

## MEDICAL INSPECTION OF SCHOOLS IN BOSTON, MASS.*

BY S. H. AYER, M.D.,
*Formerly Chief School Physician of Boston.*

WHEN I accepted the invitation sent to me by the secretary of the Boston 1915 Health Conference to speak before your association on the subject of the Medical Inspection of School Children, I supposed that my resignation of my office as chief school physician of Boston, which was accepted by the Board of Health, Feb. 3, was known to your secretary.

I was, therefore, a bit surprised, upon receiving the official notice of this meeting, to see following my name the title, "Chief School Physician of Boston." It seems to me proper, therefore, before making any remarks this afternoon, to have it clearly understood that I am not at present the chief school physician of Boston (as indicated by the notice). I will further state that my resignation was largely due to the fact that I could not afford to take necessary time from my private practice to fill the position in view of the slender salary it carried.

This subject of medical inspection of school children is so extensive, and has made such strides throughout the entire country during the last decade, that it will be impossible in the time allowed me to present it in any other than a general way.

*First conception of the work.* — Boston has the honor of being the pioneer in this work, and the thanks of the community are due primarily to Dr. Samuel H. Durgin, for many years chairman of the Board of Health, who first suggested it and then carried it into practical effect. This, however, he was not able to do without much effort, for it was a difficult undertaking to make those in authority recognize its value. It was another example of a man being ahead of his time.

About three years afterwards medical inspection of school children was started in New York City, representatives were sent to Boston to gather information of the way the work was carried on here, and Dr. Durgin was only too glad to enlighten them.

No one will question the value of this medical inspection of school children. At a meeting of the Alumni Association of the Boston City Hospital, held in this city last week, I was pleased to hear Dr. Charles W. Eliot say that he considered "the medical inspection of school children of the utmost importance," not only to the children of the present time, but to the coming generation, and he predicted that in thirty years from now there would be such marked changes among the school children both in bodily and mental vigor, due to this medical supervision, as can hardly

* Read at the Health Conference of the 1915 Movement, February 1911.

be foreseen at this time. He further said that the work required the employment of highly trained men and that it was noticeable that the health officers throughout the country were being better and better paid for their services.

*Lack of progress in Boston.* — Although Boston was first in this work, I am sorry to be obliged to admit that she has been outstripped in it by nearly all the large cities in the country who have taken it up. Indeed, she has not merely been outstripped, but almost left at the post, for there have been very few improvements in the methods of the school physicians of Boston since the work was begun some sixteen years ago. The men who are doing the work to-day are practically doing it in the same way as the men performed it in the beginning. This lack of progress has been due to a variety of reasons, and although the work has been under the supervision of the Board of Health, I do not hold it nearly as much responsible for this standing still as I do the politicians who have interfered with or controlled the board for their own purposes.

The Bureau of Municipal Research of New York City upon April 1, 1910, published data relative to the examination of school children for the following conditions:

Cities in which school children are examined for:

(1) Transmissible diseases.
(2) Defective vision.
(3) Breathing troubles.
(4) Defective teeth.
(5) Tubercular symptoms.

Cities reporting co-operation between schools and local dispensaries and hospitals:

1. One or more school nurses.
2. Instruction of parents in physical care of children.
3. Circulation of cards of instruction among parents.

In looking over this tabulation, I find the following cities were at that time ahead of Boston in considering these methods of inspection:

| | |
|---|---|
| California, | Berkeley and Pasadena. |
| Georgia, | Atlanta. |
| Maryland, | Baltimore. |
| Massachusetts, | Lowell. |
| Michigan, | Detroit. |
| Minnesota, | St. Paul. |
| New Jersey, | Jersey City and Newark. |
| New York, | Ithaca and Rochester. |
| Pennsylvania, | Pittsburg. |
| Washington, | Seattle. |

Cities doing practically the same amount of work as Boston at that time are:

Waltham, Mass.
St. Louis, Mo.
Cleveland, Ohio.
Newport, R. I.

Comment upon this tabulation is unnecessary. The facts speak for themselves and they show us where Boston stood April 1, 1910, in regard to medical inspection of school children.

*Political interference.* — Many times the Board of Health have endeavored to obtain funds to enable them to further this work, only to have the blue pencil drawn ruthlessly through their just demands. The work has also been seriously impaired by the appointment as school physicians by the mayor of men who, in the opinion of the board, were unfit for the work.

This is not only radically wrong, but an extremely short-sighted policy, and it is to be sincerely hoped will never occur again. Such action is not only an insult to the efficiency of the Board of Health, but a detriment to the health and physical welfare of the children of the citizens of Boston attending the public schools. At this point, I think it would be proper and right for me to say that the Board of Health of this city is, in my opinion, very far from being efficient, that its inefficiency is largely due to the fact that its members are too frequently changed. Can you conceive of any large business corporation every few years changing the personnel of its management for purely political reasons? Yet this is what has been done for years in the Boston Board of Health. What are the results?

The results are that new members of this board have no sooner been broken in to the duties of their position than they are removed from office by an incoming administration, whose appointees are in turn treated in a like manner a few years later. This means that the city is obliged to submit to an inferior management of its health department. In other words, your health as well as that of the entire community is being trifled with for merely political motives.

Again, the valuable time of the chairman of the board is being unnecessarily used in instructing these new members regarding their respective duties, time for which the citizens of Boston are paying in order to protect their health, and not in order that it be wasted in this way. Furthermore, if there is any friction among the members of the board, the chairman, the man whose opinion should prevail, is apt to find himself in the minority. How long would any progressive business manager of a business corporation stand such a condition of affairs? And if the corporation failed to earn the expected dividends, who would be to blame?

*Reorganization of Board of Health necessary.* — Now to overcome this condition, the head of the Board of Health should be one man, instead of three, and he should be given full power to manage his department to the best of his ability. He should be a man of the utmost intelligence as regards measures pertaining to health and should be paid a salary commensurate with the demands of his office, and be granted a liberal pension at the end of a certain period of service, which pension should be sufficiently large to make the position sought by the best brains on health problems in the country. Such a man should have able lieutenants to assist him in carrying out his plans, but these assistants should be of his own choosing and subject to his orders, he being held responsible for their acts.

So, then, make the Board of Health under one head, as has recently been done in other departments, place the responsibility for outlining and

carrying into effect the work of this department upon his shoulders, and if he does not succeed in "making good," look for a suitable successor. By such a plan the city will secure the best services, and, to my mind, by no other.

Until an arrangement of this kind is brought about and removed from politics, Boston must necessarily suffer from a markedly inferior administration of its health department.

Do not understand me at this time to be reflecting upon the ability of the present members of the Board of Health. Such is far from my purpose. I should like also to add that it is my opinion, as well as that of many other physicians in Boston, that there are other departments in this city now running under separate supervision that should be under the Board of Health,— the Consumptive Hospital, for example.

*The Boston school physicians.* — But now to return to the subject matter. The school physicians of the city of Boston are, as you are all aware, under the supervision of the Board of Health. The school nurses are under the supervision of the School Committee. During the past year I have given a great deal of thought to the subject of a plan whereby the school physicians and school nurses might satisfactorily carry on their work under the existing régime, and I have concluded it to be an absolute impossibility.

It is extremely unfortunate that such an arrangement should ever have been allowed. The school physicians and school nurses should both be ultimately responsible to the same head, the Board of Health; that is, the nurses should be under the immediate direction of the school physicians, and the school physicians should be responsible to the Board of Health for the carrying out of the work. Under the existing arrangement, there is necessarily much waste of time, actual reduplication of work by both physicians and nurse, and unnecessary using up of the children's hours of study. I know of no other city where such a condition exists, and until it is changed here and both the physicians and nurses are placed under one head, Boston will continue to be most seriously handicapped.

*Selection of school physicians.* — Work of this kind is of such value and importance to the welfare of the school children that extreme care should be insisted on in the selection of physicians receiving these appointments.

How then should these men be appointed?

I can see no reason why men appointed to the positions of school physicians to the city of Boston should not be obliged to pass a most thorough and rigid examination. These examinations should be carried on by physicians who should not be in any way hampered by politics. It is my belief that an examining board made up from representative physicians of Boston could be obtained without expense to the city, examination of candidates being held two or three times a year. I believe that reputable physicians could be found who would esteem it an honor to serve upon such a board. Under the existing conditions, I understand that the mayor's office is at times literally besieged by politicians endeavoring to obtain these appointments. Such condition of things is wrong and should not exist. Men receiving these appointments should obtain them on their merits, as do the house officers of the Boston City Hospital and the Massachusetts General Hospital, who are appointed to positions by the board of trustees of those institutions after competitive examinations.

*Security of appointments.* — Upon receiving such an appointment, after passing a satisfactory examination, a physician accepting the same should be given a feeling of security. He should not be continually made to feel that at any moment he is liable to be removed from his position without cause. In New York City these appointments come under the control of the civil service. Not only should these positions be made secure by an arrangement of this sort for the school physicians, but the same rule should apply to everybody from the chief school physician down through his various assistants.

Arrangements should be so made that the mayor should have nothing whatever to say about these appointments. They are out of his line. The ordinary mayor is not trained in such matters. His opinion regarding the fitness of a candidate for medical work is comparatively of no value, and the city is a loser by his having anything to say about it. In my opinion, too, the mayor should not desire to have anything to say regarding it, should welcome any change that would relieve him. It seems to me that if he could be relieved of this responsibility, if he could say to these petty, plausible, persistent politicians, continually coming to him to seek these appointments, that the matter was entirely out of his hands, it would be a saving to him of a great deal of brain fag and at the same time furnish him with just so much more time to devote to things that really need his oversight. I have no doubt that he would welcome such a change.

Such a plan as this exists in the Post-Office Department of the United States, and I have been told by a recent postmaster of Boston that the relief that such an arrangement afforded him could hardly be estimated.

*Salaries.* — We come now to the remuneration for the services rendered by the school physicians. Boston has ever since this movement of school inspection started been practically receiving charity from the men doing this work. Now although Boston is very much in debt, very much behind in its financial obligations, nevertheless I do not believe it would be the popular wish of the citizens of Boston that the hand of charity should be held out to enable the city to carry on their school inspection work. One man who has been doing this work ever since it started said that he took the position because he wanted to see what was going on in the schools; he wanted to know how his children were being taken care of, and after getting into the work he became so interested in it he was very loath to give it up. I have no doubt that this opinion prevails in the minds of a very large number of school physicians

of Boston to-day who have children attending the public schools. The work is interesting, it is highly interesting. Before being appointed chief school physician, I myself filled such a position for fifteen years. Although the work at times seriously interfered with my private practice, I disliked abandoning it. But we are now coming to a time when a change has got to be made.

When the work started, it was new, it was untried, the value of such work could not readily be estimated. The Board of Health could not at that time determine what salary should be paid for such services. Nevertheless, it was not long before they discovered that the salaries that were being paid to these physicians for this work were entirely inadequate and accordingly efforts were made, from time to time, to increase the salaries, only, however, to be turned down each and every time by those in power and authority.

Now a new deal is contemplated and it seems to me, although in early days other cities came to Boston for the purpose of learning what they could regarding this work, Boston can very well investigate the salaries that are being paid for this work in other localities. I believe that I am safe in saying that there is no city compared with Boston in size where the salaries paid for this work are so small. Last fall it was proposed to reduce the number of inspecting physicians to forty and pay them $1,000 a year. Now I hear it has been decided to pay $500 yearly, a much less salary, and retain the original number, namely, eighty men, to do the work. The salary is not sufficiently large to secure good men and demand of them two hours of daily service. To be sure, there will be plenty of applicants for the positions at this salary, but the applicants must be of inferior grade. The consequence will be that the work will not be thoroughly done. The school work is bound to increase rather than diminish. One thousand dollars would be very small compensation for the services rendered.

If private individuals in case of illness seek out the best medical aid possible for their children, why should the municipality offer an inferior article for their children in the schools? There is, to my mind, no satisfactory answer to this question.

*Situation in New York City.* — Perhaps it would be interesting at this point if I were to state the salaries paid in New York City for this work. They are as follows: Chief school physician, salary of $3,000 a year and the use and upkeep of an automobile.

There are five borough chiefs, so-called, who receive salaries as follows:

| | |
|---|---|
| Borough chief of Manhattan, | $2,550 |
| Brooklyn, | $1,950 |
| Richmond, | $1,500 |
| Queens, | $1,500 |
| Bronx, | $1,500 |

In addition to this, they have a division termed supervising medical inspectors consisting of six men. These receive $1,500 a year. Following these come the 141 medical inspectors whose work corresponds to our school physicians. They receive $1,200 each per annum. For this work these men are compelled to give all their time between nine and twelve o'clock every day in the week, including Saturdays, the first five days being devoted to the schools and, as I understand it, the Saturdays to visiting the homes.

Boston, of course, does not require such a large force of men to do the work, but they require a chief school physician, who should have at least two assistants to carry out his orders. There is no reason, to my mind, if the men appointed to fill these positions in Boston devote as much of their time to the work as the men in New York, why they should not receive as high a salary. In Cleveland, Ohio, salaries for doing the work are exceedingly large. Even at $1,200 per year for a medical inspector it would be impossible for many of the men now doing the work to retain their positions on account of serious interference with their private practice. Such was my own reason for handing in my resignation.

*Ridicule should be avoided.* — Therefore it seems to me that Boston does not want to have the finger of ridicule pointed at her any longer by these progressive cities to the west of us. Boston cannot afford to be made the laughing stock of the whole country by pleading poverty at this time.

*Increase taxes if necessary to raise funds.* — I do not think it would be wise for Boston to increase the debt to enable them to further this work, but there is no reason whatever why the necessary funds should not be raised by direct taxation. What does it matter if the tax-rate is increased a few cents more or less, if by so doing we are looking out for the health of our school children? How could money be better employed? I do not believe there is a taxpayer in Boston who would come out and object to an increase in the tax-rate of this city caused by the raising of funds to enable the city to better the physicial condition of the school children, who will become its future citizens. It is absurd for any managing body of any city to try to keep down the tax-rate with no better excuse than this. So, in my opinion, enough money should be provided by the city to pay salaries for this work sufficiently large to enable the securing of the very best men.

*Politics.* — A few days ago, a prominent young physician of Boston told me that when the proposed change of raising salaries to $1,000 per year was talked of, he was approached by a man who asked him if he would like one of these positions. This physician decided he did not care for it. "What," said the man, "would you not care for a position at $1,000 per year?" "No," he replied, "I do not think I could give the necessary time." "Well, if you want it, I can fit it for you," was the reply. That man was a politician. It is deplorable that such a condition of things as this exists in this or any other city. Until, as I have said, some arrangement is made whereby this work can be removed from politics, such incidents as I have related are bound to be of common occurrence.

*Conclusion.* — It is my hope that in any reorgan-

ization of this work in Boston, those having authority will wake up to the fact that they must be willing to pay for what they get. They must so arrange the work that the men appointed to these positions cannot in any way be secured by "pull" of the political heelers, and that the whole arrangement of the school work will be so constructed as to remove City Hall from any say in the matter whatever. Also, that the work shall be so planned that the nurses and the school physicians will be under one head, and not, as at present, under the supervision of two bodies, namely, the Board of Health and the School Committee.

All medical schools should have a course especially designed to train students for positions in medical school inspection. This course should be most comprehensive and thorough. Arrangements should be made in all the large cities where such courses are held for the students to receive practical demonstrations from time to time in the public schools.

## Clinical Department.

### A SIMPLE, QUICKLY REMOVABLE HEAD BANDAGE.

BY EBEN C. HILL, M.D., U. S. A.

(Published with the consent of the Surgeon-General, United States Army.)

IN treating a recent case of gunshot injury to the lower maxilla in which a portion of the bone was destroyed and wiring was demanded, I had occasion to redress and irrigate the wound several times a day. A firm bandage was needed to support the jaw until bony union took place, and

Head bandage.

any of the usual head bandages required considerable time to adjust and were difficult to maintain in the same position. Should the bandage become loosened during sleep, then the necessary support was lost until the part was rebandaged.

The photographs show an improvised arrangement by which I obtained ready access to the part, any desired degree of pressure on the maxilla and an easily adjusted and secure bandage. All that was needed was an ordinary surgeon's cap of unbleached muslin, three safety pins and a strip of gauze.

Head bandage.

I believe that this bandage could be successfully employed in many other instances of head injuries in place of the more cumbersome Barton or other head bandage.

## Reports of Societies.

### BOSTON MEDICAL LIBRARY IN CONJUNCTION WITH THE SUFFOLK DISTRICT MEDICAL SOCIETY.

MEETING OF DEC. 21, 1910.

DR. JAMES P. TUTTLE, New York, read a paper on

FIBROUS STRICTURE OF THE RECTUM.[1]

DISCUSSION.

DR. F. J. COTTON. My experience with these benign strictures has been small and most of those I have seen have been of the post-operative type.

Out of a total of eight, one has resulted from scar contraction in a cancer excision (this case is still in progress of dilatation). Three had followed hemorrhoidal operations (all yielded promptly to treatment with dilators), one followed the general scar contraction of a huge dissecting ischiorectal abscess (but yielded readily to dilatation), two were associated with rather extensive rectal tubercular infiltrations (these were little benefited by any treatment), while one only seemed the result of a real primary periproctitis, assumed to be of syphilitic origin. This last case refused treatment.

I have had no cases calling for very radical treatment.

I was rather surprised at the writer's advocacy of a colostomy high up in the transverse colon; from my experience of the Quénu (or Mayo) operation for cancer, I have felt that a preliminary colostomy in the descending colon (provided said descending colon

[1] See JOURNAL, p. 445.

was well dragged down) offered no obstacle to the later operation.

Dr. F. B. Harrington: An examination of the records at the Massachusetts General Hospital indicates that nearly 75% of the cases of non-malignant stricture of the rectum occur in women. It is an interesting fact that the cases of cancer of the rectum in the same institution show nearly three times as many in the male as in the female.

About 90% of the non-malignant strictures in women occur in those who have been married.

These facts suggest that the trauma of childbearing is a potent cause.

In women, also, the opportunity for local infection of the rectum by gonorrhea and syphilis is greater than in men. Proctitis from any cause, whether traumatic, catarrhal or ulcerative, may invade the submucosa, the muscular coats and the perirectal tissues, producing stricture, as the same processes do in other parts of the alimentary canal, for example, the esophagus, the duodenum and the appendix, or as inflammation and trauma do in the urethral canal.

The influence of syphilis in producing stricture of the rectum has been overestimated. I recall but one case in a considerable number which have come under my observation in which syphilis existed, and in this case it was not proved as a cause.

I have never seen a case of complete obstruction of the bowels in a case of stricture of the rectum. I have thought that this resulted from the more fixed condition of the walls than that which exists in the intestine higher up.

My treatment has been largely conservative. I use bougies and teach patients to use them. I have cut narrow strictures in a few instances with benefit. In two cases with extensive ulceration and stricture I have done colostomy, restoring the patients to comparative health from conditions of great debility and wretchedness.

One of these cases I have followed for five years hoping for such improvement in the rectum that restoration of the natural channel would be justified. In this case the ulcerations have healed, but the stricture of the rectum has become so extensive and so tight that operation of restoration is not possible.

This would seem to be a desirable case for operation of extirpation of the rectum proposed by Dr. Tuttle.

Dr. Charles L. Scudder: I understand that by non-malignant stricture of the rectum is meant a stricture of inflammatory origin. The primary cause of the inflammation may be a simple infection or an infection from tuberculosis or syphilis.

The pathological change common to those three types of infection is the formation of much fibrous tissue in the submucous and muscle layer of the intestinal wall. The pathologist is often unable to state with accuracy whether or not the tissue submitted to him from the stricture is of tuberculous or syphilitic origin. All traces of the initial infecting agent may be wiped out.

If tuberculosis or syphilis is known to be present in the patient with rectal stricture it is presumptive evidence that the stricture is dependent upon that particular disease. It is possible that a stricture of simple inflammatory origin may exist in a tuberculous or syphilitic individual.

It is conceivable that if these cases of stricture of the rectum were seen in the initial stage of the disease before the narrowing of the bowel has occurred, certain of these cases might progress no further. The employment in these cases of hygienic care with regard to food and bowel movements, the efficient dilatation of the bowel not yet much constricted, and anti-syphilitic treatment, — the employment of these three measures should in a few of the early cases check the progress of the disease and the most distressing obstructive stage of rectal stricture might be avoided.

Obstructive stricture of the rectum is a terrible disease. It is insidious in its onset, it is ever increasingly difficult to satisfactorily treat.

I have carefully searched the records of the Massachusetts General Hospital from 1872 to 1909 inclusive for cases of benign rectal stricture. I find that there is a total of 124 cases. This is not a large number to have entered the hospital in thirty-seven years. It is an average of a little more than three each year. There is no doubt but that if more satisfactory treatment could be offered these cases than is offered at present, there would be a larger number seeking relief at our general hospitals.

Each of these 124 cases represented the usual terminal condition in the disease under consideration, that is, each case was suffering from rectal obstruction. There were no cases in the early stage of the disease. There were a few cases in the ulcerative stage with discharges of mucus, pus and blood from the rectum, but the obstructive symptom was that from which relief was sought in every instance.

Of these 124 cases, 85 were women, 39 were men.

Of these 124 cases, the cause of the stricture was not discoverable in 18.

Syphilis was the probable cause in 57 cases.

Tuberculosis in two cases seemed to be the primary factor in the etiology.

The stricture followed perirectal abscesses in 12 cases and fistula in ano and perirectal abscesses in 23 cases.

Two cases gave a very definite history of dysentery. One of these patients lived in the Philippines at the time of the dysentery.

Stricture of the rectum followed in one case a complete tear of the perineum. This tear extended through the rectal sphincter.

In one case stricture followed the wound caused by sitting upon a nail.

In 6 cases it was discovered that a former operation for hemorrhoids had been performed. What operation was done was not stated. The symptoms in these cases dated from the hemorrhoidal operation.

There were 2 cases of congenital occlusion of the rectum.

Thus, in these 124 cases, a simple infection, tuberculosis and syphilis form the chief etiological factors. From an etiological point of view this series of cases is certainly fairly representative.

*Treatment.* — Ninety-eight of these 124 cases were treated by simple dilatation of the rectal narrowing. Dilatation was and is the leading method of treating these cases of benign rectal stricture.

Great improvement in recent years has taken place in the exact method of dilatation, so that the risks of dilatation are very much diminished.

In 1872 the dilatation of a rectal stricture was in some cases rather a blind method. In these 98 cases dilated with bougies there were 6 deaths apparently attributable to the dilatation. These deaths occurred within three days or so of the operation and were associated with chills, nausea and vomiting and abdominal distention and tenderness. Evidently the deaths were due to peritonitis occasioned by the passage of the bougie either through the rectal wall or so damaging the rectal wall that a fatal peritonitis followed.

There were 5 cases of recto-vaginal fistulæ associated with rectal stricture.

Those cases operated upon by some more radical procedure than simple dilatation were as follows:

Four strictures were removed, one by the perineal route, one by the sacral route without previous colostomy, one by the sacral route with subsequent colostomy, one by the sacral route preceded by a colostomy.

On one case a proctoplasty was done through a sacral incision followed by a colostomy.

One case had a partial proctotomy done.

One case was excised by Whitehead's approach.

All of the strictures in this series of cases were within 2½ inches to 3 inches of the anal margin.

Up to 1890 only a very few cases of excision had been done in any clinic.

The operative procedures in these cases were done comparatively recently. The earliest noted in this series at the Massachusetts General Hospital was that done in 1903. This is about the time that the Germans were first very generally operating upon these cases.

The analysis of this series of cases and their treatment not only illustrates the etiology and pathology of this distressing disease as it is understood to-day, but such a review discloses the fact that excepting electrolysis and cauterization, all methods have been tried at the Massachusetts General Hospital clinic including, (1) partial proctotomy, introduced by Stafford in 1834, comparable to the operation of internal urethrotomy; (2) including complete proctotomy introduced by Humphries in 1856, and (3) including excision done in 1825 by Lisfranc.

The results in the operative cases known are only temporary relief, and later a recurrence of the stricture necessitating the continual employment of bougies.

Mention must be made here of the procedure described by Lothrop [2] in which a proctoplasty was done by an anterior route in a female patient after separating the posterior vaginal wall from the rectum. All of these methods have been found more or less unsatisfactory.

In many cases the stricture has recurred and has sometimes been much more severe than it was previous to operation.

From the work of Tuttle, Thiem and Lowson and others it would seem that in a benign stricture of the rectum in the lower few inches inoperable by excision or proctotomy, or when it has recurred after these operations, a colostomy securing rest to the part and dilatation of the stricture from above may be successful treatment.

That colostomy has a lasting beneficial effect upon the stricture in addition to its palliation of the symptoms of obstruction, that excision of the stricture is usually unsatisfactory and that the complete perineal extirpation in certain cases is a satisfactory operation, these three facts seem to me to be those from Dr. Tuttle's paper upon benign stricture of the rectum which call for especial emphasis.

DR. T. CHITTENDEN HILL: In closing this discussion, I wish to say that I am heartily in accord with the position taken by Dr. Tuttle in his paper, that a total extirpation is the only procedure which offers much hope of a permanent cure.

Also I wish to express my entire faith in the work done by Dr. Tuttle, and congratulate him on his low mortality of but 6%, an improvement on the immediate mortality as taken from the literature, which varies from 12 to 18%.

I have seen him on several occasions do his operation, and in other cases have seen the results of his work.

It must be remembered that he has done this operation a great many more times than most surgeons, and when we take into consideration his large experience with the operation in cancer of the rectum, his results, while the best yet reported, are not greatly to be wondered at.

I believe this large mortality is in a measure avoidable, if the technic of the operation as described here to-night were more carefully followed. The success of this operation in addition to a wise selection of cases is attributable chiefly to two things, first, an aseptic technic, and, secondly, to a high loosening of the rectum.

The very first step of dissecting a cuff of mucous membrane at the anal orifice, and tying a string about it and cauterizing the end, insures an aseptic technic, always providing one does not tear or puncture the walls of the gut later, and that there are no fistulous sinuses in the immediate vicinity that will infect the field of operation. These adjacent infections can usually be determined by the amount of purulent discharge previous to operation and should always be taken into consideration before advising an extirpation.

In addition to the aseptic technic, by crowding back or opening the peritoneum and dividing the lateral attachments, one is able to free the rectum high up so that it is possible to get well above the strictured area and bring the gut down so that it can be amputated above the stricture and united without tension at the anus.

Dr. Cotton has stated that he cannot see the advantage of attempting to remove long sections of the rectum by the perineal route, but would prefer the combined method as advocated by the Mayos.

In his paper Dr. Tuttle has advocated the combined method as well, but, as a matter of fact, in the great majority of strictures, it is not necessary to subject the patient to so severe an operation. The combined operation has many advantages in carcinoma of the rectum, such as removing involved glands, etc., which are of no consequence in the treatment of benign stricture.

Therefore, if the strictured area can be readily removed from below, it is the safer method and answers every purpose as well.

In reference to what Dr. Cotton has said about its being unnecessary to do a colostomy in the transverse colon, I would say that in the majority of cases it probably is not, but one never knows beforehand the length of the sigmoid. In some cases it may be three feet, while in others it may be very short, making it impossible to pull the bowel down to the required extent when it is attached above to the abdominal wall.

Dr. Tuttle has called attention to some of the dangers in connection with removal of cicatricial stricture and that this method is not suitable in cases of extensive ulceration and suppuration of the rectum.

In an extirpation, the internal sphincter and levator ani muscles are always sacrificed, and although the external sphincter is preserved and in the majority of cases prevents incontinence, still, the resulting condition is more or less an artificial one. Its great advantage is that it is in the normal position and patients prefer it to an inguinal anus.

For *this reason, I believe that* in uncomplicated strictures one is never justified in resorting at once to operative measures, until gradual dilation with bougies has been tried.

The *duration of the stenosis* is an important factor in the amenability to dilation, but there are very few cases in my experience that are not improved, and some cases can be made perfectly comfortable for years.

The dilation should be carried on with gentleness and persevered in until the stricture has been dilated sufficiently to admit easily the ordinary index finger. This is *quite enough* for the purpose of effective de-

[2] BOSTON MED. AND SURG. JOUR.

fecation if kept at this diameter by passing the bougies at such intervals as are found necessary.

Some surgeons dilate to 1½ inches, but this is liable to split the walls of the gut and set up perirectal suppuration, causes pain and more or less discomfort without affording compensating benefits.

*I wish to speak of the fact mentioned in the paper* regarding stricture of the rectum following hemorrhoid operations and that cases operated should be watched carefully whatever method is used for removing them, if there seems to be any tendency towards stenosis.

I have now under treatment a case of annular stricture at the level of the internal sphincter that would barely admit a No. 3 Wales bougie that was caused by a Whitehead operation. As attempts at dilation were painful, the stricture was divided on both sides and posteriorly.

As this case came under observation four months following the hemorrhoid operation, I believe this simple measure will effect a cure.

As *another instance* of the importance of keeping track of *hemorrhoid* cases, I wish to report another case.

The following notes were furnished me from the surgical records of one of our large hospitals: "G. R., married, age twenty-two, admitted to hospital Sept. 28, 1903. Present illness: For two years patient has been troubled by itching and bleeding about her anus with much pain on defecation unless she keeps movements very loose. Sept. 29, operation by clamp and cautery for hemorrhoids. Oct. 5, discharged well." June 5, 1906, two years and nine months later, I saw this case through the courtesy of Dr. Stuart, of South Boston. At that time, she was in a miserable condition, had lost 26 lb. in weight, and had a profuse mucopurulent bloody discharge associated with a great deal of straining and tenesmus. The act of defecation had gradually become very difficult and irregular, necessitating a variety of purgatives, which afforded little relief. Because of the muco-purulent accumulations she was obliged to go to the toilet frequently during the daytime, and three or four times every night. A digital examination revealed a dense tubular stricture two inches above the anus that would not admit the index finger.

I advised and began gradual dilation which afforded her much relief from tenesmus and painful defection, but the rectal ulceration as evidenced by the large amount of mucopurulent discharge continued, and her general health was so wretched that I performed an inguinal colostomy five months later, after which she regained her normal health in a short time.

This case is simply cited to call attention to the importance of passing the index finger to its full length into the rectum on the tenth or twelfth day following a hemorrhoidal operation. If no constriction is felt at this time, it is most improbable that any will take place, but if one is found, simply the introduction of the finger at intervals of five days for a period of two or three weeks will prevent any contraction following these operations.

In this particular case, however, it is impossible to state positively whether the stricture resulted from the operation or whether there was then present an infective ulceration with or without a stricture which was overlooked.

The statement in her history of "bleeding about her anus with much pain on defecation unless she keeps her movements very loose" is quite suggestive of ulceration or stricture.

Two and one-half years after the colostomy she went through a normal labor and is now nursing an infant eleven months old. Although she had been married ten years, this was her first pregnancy.

## Book Reviews.

*The Bradshaw Lecture on Cancer.* By Sir ALFRED PEARCE GOULD, K.C.V.O., M.S. Lond., F.R.C.S. Eng. London: John Bale, Sons & Danielsson. 1911.

In this lecture, delivered at the Royal College of Surgeons of England on Dec. 7, 1910, Mr. Gould reviews the bearing of recent discoveries in the biology of cancer on the probable nature, causes, curability and prevention of malignant disease. His conclusion that cancer is neither an infection nor an embryonic reversion, but a "breach or failure of fundamental cell law," hardly brings us nearer a solution of the problem, however, and is as unsatisfactory as most negative definitions.

*Diseases of Children for Nurses.* Including Infant Feeding, Therapeutic Measures Employed in Childhood, Treatment for Emergencies, Prophylaxis, Hygiene and Nursing. By ROBERT S. MCCOOMBS, M.D. Illustrated. Second edition, thoroughly revised. Philadelphia and London: W. B. Saunders Company. 1911.

This textbook in pediatrics for nurses, one of a series issued by this firm, originally published in 1907, has now reached its second edition. It has been extensively revised, and the chapters on artifical feeding of infants and on intestinal diseases and therapeutics have been especially amplified and improved. The book, which was developed from a series of lectures to nurses at the Children's Hospital of Philadelphia, should be serviceable to teachers as well as to pupils and graduates. Its arrangement is excellent, and its illustrations many and admirable.

*Annual Report of the Surgeon-General of the Public Health and Marine-Hospital Service of the United States.* For the fiscal year 1909. Washington: Government Printing Office. 1910.

This somewhat belated report, dated Nov. 30, 1909, describes the operations of the Public Health and Marine-Hospital Service from July 1, 1908, to June 30, 1909. The activities of the Service are numerous and varied, including domestic, insular and foreign quarantine, medical inspection of immigrants, and a large amount of scientific research and sanitation. The report contains much interesting and valuable information on a variety of special topics, with many tables of statistics. At its conclusion, the surgeon-general, Dr. Wyman, emphasizes the need of the Service for "enlargement of its facilities for furnishing information by distribution of its reports and other publications."

THE BOSTON

# Medical and Surgical Journal.

THURSDAY, MARCH 30, 1911

*A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.*

*All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.*

*Remittance should be made by money order, draft or registered letter payable to*

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

## GARTH, DRYDEN AND "THE DISPENSARY."

IN his scholarly and interesting address before the Boston Society for Medical Improvement, on March 20, on "The History of the Royal College of Physicians of London," Dr. Thomas McCrae, of Baltimore, took occasion to refer to Dr. Samuel Garth, a distinguished member of the college, who played a prominent part in two notable episodes connected with that institution. This Dr. Grath, who constitutes a most picturesque and characteristic figure from the late Restoration and early pre-Georgian era, is one of an unfortunately limited number of men who have achieved reputation both in medicine and in literature, though his distinction in the latter field is due chiefly to a single poem. The details of his life have been most admirably presented by Dr. Harvey Cushing, of Baltimore, in a paper read in 1904 at a meeting of the Johns Hopkins Hospital Historical Club, and published in the *Johns Hopkins Hospital Bulletin* for January, 1906.

The first of the above episodes with which Dr. Garth was connected was the "dispensarian quarrel." In the latter part of the seventeenth century, contention arose between the physicians and the apothecaries of London, on account of the latter's custom of dispensing medicines directly to the poor, thereby keeping them from medical clinics, and pocketing the fees. The contestants were headed on the one side by the College of Physicians, on the other by the Apothecaries' Hall. The affair finally came to a riot in Warwick Lane and was ultimately settled in favor of the physicians. Garth celebrated it in a mock-heroic poem, "The Dispensary," which was first published in 1699 and went through a number of editions in a few years. Written in heroic couplets, with more of Dryden's ruggedness than of Pope's finish, the poem sounds monotonous and conventional enough to our modern ear; yet some parts of it are excellent descriptive verse notwithstanding. Most famous perhaps are the following lines:

"Febris is first: The Hag relentless hears
The Virgin's Sighs; and sees the Infant's Tears.
In her parch'd Eyeballs fiery Meteors reign;
And restless Ferments revel in each Vein.
Then Hydrops next appears amongst the Throng;
Bloated, and big, she slowly sails along.
But, like a Miser, in Excess she's poor;
And pines for Thirst amidst her wat'ry Store.
Whilst meagre Phthisis gives a silent Blow;
Her Stroaks are sure; but her Advances slow.
No loud Alarms, nor fierce Assaults are shown:
She starves the Fortress first; then takes the Town."

The second episode in which Garth was associated with the College of Physicians was Dryden's funeral. The poet laureate died on May 1, 1700. For some unknown reason his body was refused a public lying-in-state; and Garth, out of regard for his poetic master, procured its transference to the college, where, on May 13, he pronounced Dryden's funeral oration, a very fine prose composition. Invitations were issued by Garth to a number of friends "to Accompany the Corps of Mr. John Dryden, from the College of Physicians in Warwick Lane, to Westminster Abby"; and there "the corps" was "quietly inurn'd" in the Poets' Corner where now it rests.

This association of Samuel Garth with Dryden and with the "dispensarian quarrel" makes him interesting both as a poet and as a physician. In his sketch of Garth, in "The Lives of the Most Eminent English Poets," — to which we referred in last week's issue of the JOURNAL in an editorial on "Dr. Johnson and the Medical Profession," — Johnson says that Garth "was so much distinguished, by his conversation and accomplishments, as to obtain very extensive practice. He was made Physician in Ordinary to the King and Physician-General to the Army." For several reasons, then, Dr. Garth may well be remembered by the profession as one of its distinguished and interesting members.

## BERNARD SHAW AND THE DOCTORS.

PROBABLY few persons in the modern literary world, not even excepting Hall Caine and Marie Corelli and Elinor Glyn, have been so successful in getting themselves and their work talked about

as Mr. George Bernard Shaw. Not only does he almost outdo Gilbert Chesterton in his own field of paradox, but he is a more kaleidoscopic and ubiquitous genius even than that chameleon among writers. And he has not merely surpassed the moderns, but acknowledges that he has vastly improved on the dramatic methods of Shakespeare and Euripides. He has been viewed in many lights by many critics, and has been hailed as everything from the prophet of a new religion to the very arch-enemy himself. Latest of all comes Mr. Temple Scott, who, in an article in the March number of the *Forum*, proclaims "Bernard Shaw: The Realizer of Ideals," and declares that it is because he is the most virtuous man of his age that he transgresses all the virtues.

This somewhat startling statement, — which reminds one of Pope's "so obliging that he ne'er oblig'd," — is called forth by a consideration of Shaw's latest book, containing three plays, of which "The Doctor's Dilemma" seems most deserving of attention. The dilemma is essentially this, — whether the doctor shall save from death of tuberculosis, by means of a "culture" whose use he alone understands, a noble, worthy, but unsuccessful friend, or a worthless but brilliant artist with whose wife the doctor happens to be in love. The doctor saves his friend, the artist falls into the hands of a less expert physician and dies. And the play stops inscrutably. Apart from the medical impossibility of the plot and the absurdity of depicting a physician in such a situation, the conclusion is not even convincing as to whether the doctor followed the higher or the lower code of ethics, the former being, of course, that which Mr. Shaw professes.

In the preface to "The Doctor's Dilemma," Mr. Shaw expounds his theory of the problem by explaining that the fault is with the public, which persists in idealizing the doctors, and, by expecting them to live up to impossible standards, forces them into a perpetual bluff. This somewhat "lame and impotent conclusion" hardly seems to consort with Mr. Shaw, the realizer of ideals, but so Mr. Scott would interpret it. Mr. Shaw's own attitude towards the medical profession is summed up in the fourteen conclusions and maxims with which his preface ends. In substance, these are as follows:

"1. Nothing is more dangerous than a poor doctor — not even a poor employer or a poor landlord.

"2. Of all the anti-social vested interests, the worst is the vested interest in ill-health.

"3. Remember that an illness is a misdemeanor and treat the doctor as an accessory unless he notifies every case to the public health authority.

"4. Treat every death as a possible, and under our present system a probable, murder by making it the subject of a reasonably conducted inquest, and execute the doctor, if necessary, as a doctor, by striking him off the register.

"5. Make up your mind how many doctors the community needs to keep it well. Do not register more or less than this number, and let registration constitute the doctor a civil servant with a dignified living wage paid out of public funds.

"6. Municipalize Harley Street [the chief place of residence of London doctors].

"7. Treat the private operator exactly as you would treat a private executioner.

"8. Treat persons who profess to be able to cure disease as you treat fortune tellers.

"9. Keep the public carefully informed by special statistics and announcements of individual cases of all illnesses of doctors or in their families.

"10. Make it compulsory for a doctor using a brass plate to have inscribed on it, in addition to the letters indicating his qualifications, the words, 'Remember that I, too, am mortal.'

"11. In legislation and social organizations, proceed on the principle that invalids, meaning persons who cannot keep themselves alive by their own activities, cannot, beyond reason, expect to be kept alive by the activities of others. The theory that every individual alive is of infinite value is legislatively impracticable. The man who costs more than he is worth is doomed by sound hygiene as inexorably as by sound economics.

"12. Do not try to live forever. You will not succeed.

"13. Use your health, even to the point of wearing it out. That is what it is for. Spend all you have before you die, and do not outlive yourself.

"14. Take the utmost care to get well born and well brought up. Be particularly careful to have this done at the expense of the nation, the chances being about forty to one against your being able to pay for it directly yourself."

These fourteen articles may be taken for what they are worth. Some are sound, some trite, some seriously absurd, some quizzical. Even the doctors can afford to be amused by them, for usually he laughs better who laughs with Mr. Shaw than does he who laughs at him.

## LEGAL STATUS OF THE BLAZEK TWINS.

In last week's issue of the Journal we commented editorially on some interesting details associated with the pregnancy, labor and puerperium of one of the pygopagous twins, Rosa and Giuseppa Blazek. Some further details relative to these sisters have recently come to hand.

It appears that a short time ago, while they were on exhibition in a music hall at Berlin, a warrant was issued for the arrest of one of them for failure to comply with a judgment awarded against her in a suit for breach of contract. Being unable to separate the sisters, the officer seized and imprisoned both. The innocent sister immediately entered suit for illegal seizure and detention of her person. The case is to be tried in court, and the counsel for the plaintiff will argue that Rosa and Giuseppa are legally separate individuals and that the government must pay damages for infringement on the rights and liberties of one of them. This raises not only forensic complications, but the interesting questions whether the husband of one of them is a bigamist, and if not, what is the relation to him of the unmarried sister.

## THE QUESTION OF DUAL PERSONALITIES.

The problem of dual personalities has long interested writers of fiction, and of fact as well, and, since the days of Stevenson, has become part of the stock in trade of many authors. It is a fairly valuable literary asset, too, for it appeals to the innate human love of the supernatural. Moreover, it has a scientific foundation, now established in general recognition since the publication some years ago of Dr. Morton Prince's monograph on the subject, which has become as much of a classic in its way as the more generally famous and familiar "Dr. Jekyll and Mr. Hyde."

An instance of popular exploitation of the theory of dual personality may be found in an article by H. Addington Bruce in the February number of the *Cosmopolitan*. The author details at length several avowedly genuine cases of dissociated personality, and illustrates them by lurid pictures from the story of Dr. Jekyll. The tale is horrible, but yet fascinating in its suggestion.

As a matter of fact, the problem of dual personalities possesses no extreme psychologic difficulties. It is now pretty generally understood that in the human brain there are continually going on mental processes outside the immediate or habitual focus of consciousness. The sum total of these processes constitutes what is known as the subconsciousness. Normally the workings of this subconsciousness are fairly well correlated with those of every-day conscious life and flow on unnoticed in a stream which at most sometimes surprises the consciousness by tossing up into it the jetsam of unsuspected thought. To this subconsciousness we spontaneously relegate our routine mental processes, and in it remain such ideas as we deliberately or unwittingly exclude from conscious attention. Now from time to to time, in the experience of an individual, it may happen that such an idea or train of ideas gets segregated by the subconsciousness and elaborated and emphasized until its results produce startling and disconcerting disturbance when reinterjected into the consciousness which had perhaps purposely discarded them. And a co-ordinated series of such trains of ideas may actually assume the rank of a separate personality, prompting the conscious self to act in a manner inconsistent with its habitual deportment. When this stage is reached the condition has become pathologic, but within normal limits every one has at least a potential secondary personality.

In this normal secondary, subordinate self probably persist not only trains of thought that have been suppressed from the actual experience of the individual, but others that have been derived from his remote ancestry. Ages ago, when man first began his toilsome upward journey from the animal state, he began to suppress thoughts and emotions which he found disadvantageous to his progress; and ever since, these primitive mental states have recurred again and again, with unabated and often irresistible power, out of the subconsciousness to which they had been consigned, and have filled his descendants with the tantalization of uncomprehended allurement back to an abandoned natural past. To these recrudescent ideas and associations we owe most of our inarticulate pleasurable emotions in our contact with the natural world, — the sight of the clouds and the sky and the sea, the sound of thunder and of the winds, the smell of flowers and of the wet earth in spring. Moreover, to them we owe our temptation to conduct which the bitter experience of the race has proved inconsistent with the social ideal of civilization. Theologically this aspect of the subconsciousness has been expressed in the doctrine of original sin. Practically, the survivals of the secondary self remain the strongest link that binds man back to his remotely animal past.

Only when the subconscious self becomes dissociated, that is, breaks loose from control and determines injudicious conduct, does the problem of dual personality become of medical importance. At other times, and in the lives of the vast majority of persons, it remains an object of interesting study and psychologic reflection, a source often of pleasure, often of poignant pain. There is something exceedingly pathetic in the picture of man painfully climbing to heights that he hardly

wished to attain, and looking back, as he often must, with regret to past human associations and possibilities now no longer possible without abandoning all he has attained, and continually hearing from his primeval but now subjugated self the call of the wild which he has forever forsaken and to which he can return only at the peril of certain destruction. Happily, however, the picture is not always so sad; for sometimes, when the dominant self goes astray, as it sometimes will, a call from the subconsciousness may bring it back to more healthful associations and enable it to start again on the true path of progress.

## PROPOSED SUBSIDY FOR CHILDBEARING IN ILLINOIS.

It is reported from Chicago that there has recently been introduced, before the Illinois State Legislature, a bill providing for payment by the state of $100 to every woman who gives birth to a child within two years after her marriage, and $100 for each succeeding child born within two years after its next older brother or sister. A higher bonus is offered for twins and triplets. The bill provides that the money for this subsidy is to be raised by imposing on bachelors of thirty-five years and upwards such per capita tax as shall be necessary to obtain the required amount.

This ingenious piece of proposed legislation is hardly likely to be enacted into law, but it is interesting as a suggestion of the direction which may be followed by popular opinion, and of measures which may be taken to encourage human reproduction and put a premium on matrimony. Similar legislative propositions have been quite frequently put forward in France.

Incidentally it may be observed that the latest school census of Chicago shows that there are in that city 5,907 families, with 7 or more living children. Of these, 1,729 have 8 children, 679 have 9, 210 have 10, 55 have 11, 19 have 12, and 3 have 13. Two thousand one hundred and forty-three of these families are Polish or German.

## ORIENTAL AND OCCIDENTAL RATES OF INCREASE IN POPULATION.

Report from Calcutta states the present population of India as approximately 315,000,000, an increase of 20,500,000 since 1901.

Report from Vienna states the present population of Austria as 28,567,898, an increase of 2,417,190 since 1901.

Report from Budapest states the present population of Hungary as 20,850,700, an increase of 1,596,000.

Comparison of these figures is instructive. During the past decade the population of India has increased about 7%, that of Austria about 9%, and that of Hungary about 8%. Undoubtedly the birth-rate is much higher in India than in either of the other countries, but its death-rate is also higher, and its net gain is, therefore, relatively less, though of course actually much more than that of Austria and Hungary, whose lower, civilized birth-rate is offset by a lower death-rate. The prolific Hindoos gain in numbers at a proportionately slower rate than do the Teutons and the Magyars.

## MEDICAL NOTES.

Pertussis in Prussia. — A communication from Berlin states that there are annually in Prussia over fourteen thousand deaths from whooping cough among infants under two years of age.

Appointment of Dr. Ziegler at Pittsburg. — It is announced that Dr. Charles E. Ziegler has been appointed director of the Elizabeth Steel Magee Hospital for Women, soon to be erected at Pittsburg, Pa. Dr. Ziegler, who is a graduate of Dickinson College, received his medical degree in 1900 from the University of Pennsylvania.

Eradication of Hookworm Disease in Belgium.— Information from Belgium states that during the past few years a vigorous sanitary, prophylactic and curative campaign among miners in Liège has resulted in reducing by over eighty per cent the amount of uncinariasis, once extensively prevalent in that province.

European Typhoid Death-Rates. — A recent article in the *Revue Scientifique* states that in France the annual death-rate from typhoid fever is 77 per 100,000 of population. In England it is 17.5, and in the Netherlands and Germany, 10. During the past seventeen years about 160,000 persons have died in France of this preventable disease.

Plague and Smallpox at Amoy. — During the fortnight ending March 25, 11 deaths of bubonic plague and 6 deaths of smallpox were reported at Amoy, China. These make a total of 25 deaths from the former and 19 from the latter disease in that city during the six weeks from Feb. 11 to March 25.

END OF CHOLERA EPIDEMIC AT HONOLULU. — During the week ending March 25, no further cases of Asiatic cholera were reported at Honolulu, and the epidemic at that port is now considered at an end. There was a total of 27 cases and 21 deaths of the disease.

SMALLPOX IN NEW BRUNSWICK. — Report from Newcastle, N. B., states that, for the past six weeks, smallpox has been prevalent in the counties of Northumberland and Kent in that province. Eighty cases of the disease are said to have occurred in the single parish of Alnwick, near Newcastle.

SCARLET FEVER AT COLGATE. — It is reported from Hamilton, N. Y., that for the past five weeks scarlet fever has been epidemic among students at Colgate University in that town. Last week occurred the first death from the disease, and as a result the college has been closed until April 4.

BUBONIC PLAGUE AT TRINIDAD. — Report from Kingston, Jamaica, states that owing to the prevalence of bubonic plague in Trinidad, a quarantine against the latter island has been established at the port of Kingston. No intelligence has yet been received of the extent or severity of the epidemic at Trinidad.

ANTI-TYPHOID INOCULATION OF TROOPS IN THE FIELD. — It is reported from San Antonio, Tex., that voluntary anti-typhoid inoculation is being extensively performed among the American troops mobilized along the Mexican frontier, especially among commands that until recently have been quartered in the North.

A PRIVATE CHARITY IN BERLIN. — Recent report from Berlin describes a private charity in that city which maintains a diet kitchen for free daily distribution of food to the tuberculous poor. Over three hundred such persons are thus supplied. The food is prepared with great care and cleanliness and distributed in sterilized tin pails either by motor or bicycle delivery wagons. Candidates for this charity are nominated by the leading physicians of Berlin.

MAXIMS OF HYGIENE FROM VIRGINIA. — The Virginia State Health Department has recently published, for distribution among the people, a series of "health maxims," some of which are as follows:

"The man who says he had rather have smallpox than be vaccinated never had the smallpox."

"An open window is better than an open grave."

"Warm rooms have killed more people than ever froze to death."

"If you let the child have measles when he is young, you may save a doctor's bill later on, but you may have to pay the undertaker now."

"A good iron pump costs less than a case of typhoid."

"If your milkman brings you warm milk, make it hot for him."

"Wire screens in the windows may keep crape from the door."

"A fly in the milk often means a member of the family in the grave."

"If some people were as much afraid of flies as they are of bad water there would be less typhoid."

"When you see a child looking like an angel, do not kiss it; you might make a real angel out of it."

"Scarlatina may not sound so dangerous as scarlet fever, but ask the undertaker."

Like all epigrams, these maxims have a tendency to overstate the facts, but they seem to contain the essence of truth; and their form, if not always elegant, is perhaps best adapted to imprint their meaning on the popular mind.

## BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, March 21, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 46, scarlatina 49, typhoid fever 11, measles 151, smallpox 0, tuberculosis 74.

The death-rate of the reported deaths for the week ending March 21, 1911, was 20.97.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, March 25, 1911, was 272, against 265 the corresponding week of last year, showing an increase of 7 deaths, and making the death-rate for the week, 20.59. Of this number 135 were males and 137 were females; 263 were white and 9 colored; 174 were born in the United States, 96 in foreign countries and 2 unknown; 59 were of American parentage, 178 of foreign parentage and 35 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 40 cases and 3 deaths; scarlatina, 48 cases and 3 deaths; typhoid fever, 10 cases and 3 deaths; measles, 168 cases and 0 deaths; tuberculosis, 90 cases and 24 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 29, whooping cough 1, heart disease 32, bronchitis

3. There were 17 deaths from violent causes. The number of children who died under one year was 51; the number under five years, 71. The number of persons who died over sixty years of age was 69. The deaths in public institutions were 120.

Diphtheria at Winthrop. — Fifteen cases of diphtheria, with three deaths, have recently been reported at Winthrop, Mass., and in consequence the public schools of that town have been indefinitely closed.

Appointment of Miss Perry at Malden. — It is announced that Miss Charlotte M. Perry, of Bennington, Vt., a graduate of the Massachusetts General Hospital Training School, has been appointed superintendent of nurses at the Malden (Mass.) Hospital.

Two Bequests to Hospitals. — The will of Mrs. George Worthington, who died recently in New York, was filed on March 23 for probate at Pittsfield, Mass., for many years her summer home. Among numerous public and private charitable bequests it contains one of $25,000 to the Children's Hospital, Boston, and one of $5,000 to the Clarkson Memorial Hospital, Omaha, Neb.

Seizure of Jelly Beans at Providence. — Report from Providence, R. I., states that, on March 23, the United States inspectors seized in that city one thousand pounds of jelly beans, a confectionery shipped there from Buffalo, N. Y., and alleged to contain talcum. This is said to be the first seizure made in Providence under the Pure Food Law.

Exhibition at Industrial School. — On Thursday, Friday and Saturday of last week, March 23, 24 and 25, an exhibit was given at the Industrial School for Crippled and Deformed Children, Boston, of the work done by pupils of the institution. Proceeds of the sale of articles made by the children will be devoted to the running expenses of the school.

Report of Boston Association for Relief and Control of Tuberculosis. — The recently published seventh annual report of the Boston Association for the Relief and Control of Tuberculosis presents a statement of the work done by the association during the year ended Oct. 31, 1910, laying particular emphasis on the actual reduction of mortality from tuberculosis in Boston and on the value of the service rendered by the Prendergast Camp at Mattapan. The actual accomplishment of the association since its organization in 1903 is summarized under fourteen headings. This progress is reviewed and the future campaign to be undertaken is outlined.

Comparative Death-Rates in Boston and New York. — Recently published comparative statistics show that during the year 1910 the total death-rate per 1,000 inhabitants was 17.25 in Boston, 15.58 in Greater Boston, 16.52 in the Borough of Manhattan and 16.1 in Greater New York. The infantile death-rates under one year of age for the same districts were respectively 3.35, 2.82, 3.62, 3.40. This comparison essentially means that Greater Boston includes more semi-rural territory than does Greater New York, and that the conditions of infantile life seem to be somewhat better throughout Boston than they are in New York.

Hospital Concerts for April. — It is announced that during the month of April, the concerts of the Boston Hospital Music Fund will be given as follows: On April 2, at the Adams Nervine Asylum, Jamaica Plain; on April 9, at the Roxbury Home for Aged Women and Children; on April 20, at the Cullis Home for Consumptives, Grove Hall; on April 23, at the Carney Hospital, South Boston; on April 27, at the New England Peabody Home for Crippled Children, Hyde Park; on April 30, at the Boston Home for Incurables, Ashmont. This is the last month of these concerts for the season.

### NEW YORK.

Lutheran Hospital. — At a meeting of the Society of the Lutheran Hospital of the City of New York, which purposes to establish a hospital and dispensary under Lutheran church auspices, Dr. George Hayunga was elected president of the society.

Hygienic Drinking Fountains. — The Board of Education has decided upon the experimental installation of hygienic drinking fountains to replace the mischief-making tin cup in the public schools. One hundred and sixty-four of these are to be placed in certain schools in the various boroughs, and if they prove satisfactory all the schools will be provided with them. The type of fountain agreed upon for the test was selected by the superintendent of buildings and sanitary superintendent Walter Bensel, of the Health Department.

New House of Chemists' Club. — The new house, on East 41st Street, of the Chemists' Club was formally opened on March 17. In

the afternoon Dr. Morris Loeb, with appropriate remarks, presented the key of the building to Dr. Russell W. Moore, president of the club, and the auditorium was dedicated to the memory of Benjamin Thompson, Count Rumford, the first great American chemist, a bust of whom was unveiled. At the evening exercises the principal address was made by Dr. Jacques Loeb, of the Rockefeller Institute. In it he gave a *résumé* of experimental work on life processes, concluding with this prophetic declaration, "By the time of the celebration of the twenty-fifth anniversary of the building we have opened to-day, vast strides will have been made toward explaining all life actions in terms of actions of inanimate substances, and physiology will be well on the way to becoming a completed chemistry." An interesting feature of the exercise was a lecture by Prof. R. B. Moore, of Butler College, Indianapolis, on "Rare Gases of the Atmosphere," in the course of which he exhibited some specimens of such gases sent from London expressly for the occasion by their discoverer, Sir William Ramsay. The new building, which has been erected at a cost of $500,000, is believed to be the first of its kind in the world, combining, as it does, all the features of a first-class social club with admirably equipped laboratories for analytical and research work.

OLDEST ALUMNUS OF PRINCETON, A MEDICAL MISSIONARY. — The ninety-sixth birthday of Dr. James C. Hepburn, the oldest alumnus of Princeton University and a noted medical missionary, who has for some years resided at East Orange, N. J., was celebrated on March 15, and among the congratulatory letters received by him was one from Governor Wilson. For five years he was settled in Singapore, but in 1846 he returned to America, and for thirteen years practiced medicine in New York. In 1859 he was sent by the Presbyterian Board of Foreign Missions to Japan, and while there he in conjunction with two others made the first translation of the Bible into Japanese. On his ninetieth birthday Dr. Hepburn was presented by the Emperor of Japan with the insignia of the third class of the Imperial Order of the Rising Sun.

FACTS REGARDING DIPHTHERIA AT THE JOHNS HOPKINS HOSPITAL. — Dr. Snow, of London, having in one of his anti-vivisection lectures in New York expressed the opinion that the recent outbreak of diphtheria at the Johns Hopkins Hospital could be regarded as a refutation of the antitoxin theory, Dr. L. F. Barker, physician-in-chief to that hospital, has published a letter in which he states that it would seem to be important to let the public know that exactly the opposite is the truth. He then goes on to give the real facts, as follows: "As soon as the presence of diphtheria was discovered, the rigid application of bacteriologic methods of diagnosis and control, and of antitoxin therapy and antitoxin immunization, — methods which we owe almost entirely to experiments upon animals, — made it possible for us not only to prevent its spread and to completely stamp out the epidemic in the hospital and medical school in a couple of weeks, but also to cure every individual infected except two, who were at the time of their infection dying, one of them from general septicemia with ulcerative endocarditis, and the other from an advanced malignant growth in the abdomen. How any one can be led to make such irresponsible statements as those which have been attributed to Dr. Snow, it is difficult for any one trained by scientific methods and with a feeling for accuracy to understand."

EMPLOYMENT LIABILITY ACT UNCONSTITUTIONAL. — The Court of Appeals has declared the Employers' Liability Act, which was passed by the Legislature last year, contrary to the Constitution of the United States and to that of the state of New York. This decision, which was unanimous, was given at Albany on March 24. It was in the suit of Earl Ives, a railroad switchman, against a Buffalo street railway on account of injuries received in the performance of his duties, and the opinion of the Court was written by Judge Werner. The so-called Workmen's Compulsory Compensation Act was passed, it may be remembered, after the subject of employers' liability had been under investigation by a legislative commission for more than a year, and its validity has been upheld by the lower courts as well as by the Appellate Division of the New York Supreme Court, although the latter tribunal was divided on the question. The Court of Appeals holds that it is not competent to impose upon an employer who has omitted no legal duty and committed no wrong a liability based solely upon a legislative fiat that his business is inherently dangerous. The possibility that he might recover the damages thus paid by means of insurance, and that he might recoup himself for the cost of insurance by an added charge to his customers, is a secondary and remote consideration that the Court thinks

cannot be taken into account in deciding whether he has been deprived of his property or property rights by "due process of law." The right of property, Judge Werner says, rests not upon philosophical or scientific speculations, nor upon the commendable impulses of benevolence or charity, nor yet upon the dictates of natural justice. The right has its foundation in the fundamental law. That can be changed by the people, but not by legislatures. If such economic and sociological arguments as are here advanced in support of this statute can be allowed to subvert the fundamental idea of property, then there is no private right entirely safe, because there is no limitation upon the absolute decisions of legislatures, and the guarantees of the Constitution are a mere waste of words. He bestows ample commendation, however, upon the legislative commission, saying: "No word of praise could overstate the industry or intelligence of this commission in dealing with a subject of such manifold ramifications and of such far-reaching importance to the state, to employers and to employees."

1. Deaver assents to the rather startling assertion of Codman that duodenal ulcer is almost as frequent as acute appendicitis. This condition has been rare in the past, simply because it has not been diagnosticated. A diagnosis can generally be made if an accurate detailed history is taken. The diagnosis of duodenal ulcer depends as almost no other disease upon the anamnesis alone. The most important symptom is dull, aching pain in the epigastrium coming on two or three hours after eating. The ulcer is situated just distal to the pylorus in the first or second inch of the duodenum, and begins as the small typical punched-out peptic ulcer. Many of these small ulcers heal spontaneously; others exist for years, giving symptoms only occasionally. Newly formed ulcers should be treated medically; chronic ulceration, surgically.

2. Lambert and Hanes have demonstrated the ameboid movement of growing sarcoma cells in vitro and suggest the importance of this discovery in the explanation of the spread of malignant growths in the tissues of the body, especially of cancer into blood and lymph spaces and serous cavities.

4. Many important points are brought out in Rodman's paper on mammary tumors. Increasing experience teaches that an accurate diagnosis between benign and malignant growths is very seldom possible. About 16% of all breast tumors are benign; about 3% are sarcomatous; the rest are malignant. But benign tumors are so liable to malignant degeneration that they should be looked upon as potentially malignant. Abnormal involution is particularly liable to end in malignancy. The author draws a very clear picture of acute carcinoma of the breast, or carcinomatous mastitis, as it is described by Volkmann. It usually begins as a diffuse rather than as a discrete process. Not infrequently it is coincident with pregnancy. It runs a very rapid course, often destroying life in six months. As regards cysts, he quotes Halsted and Bloodgood, who positively state that not a single permanent cure has resulted from operations performed in the Johns Hopkins Hospital when the carcinomatous nature of a cyst was overlooked at the time of the first operation, even though a second complete operation was done soon afterwards. Retraction of the nipple is most significant, but not, as often stated by some high in authority, pathognomonic of carcinoma.

6. McKenna states that salvarsan under no circumstances should be used without also using mercury or the

iodides. If we could conceive of making a diagnosis of syphilis so early that not a single spirochete had become encapsulated, but all lay free in the circulation, we might then expect to kill them all with one single dose, but not otherwise. We should do everything in our power to eradicate the idea that appears to have become prevalent in the minds of the laity, and some of the profession, that a single dose of salvarsan will cure syphilis permanently. The intramuscular is the safest and should be tried before using the more dangerous intravenous method.

12. Arms and Wade consider that clinical diphtheria is caused by virulent diphtheria bacilli. As a rule, following clinical diphtheria, the organisms retain their virulence as long as they persist. Virulent and avirulent bacilli are not generally found in the same case. In outbreaks of the disease a large percentage of "carriers" harbor virulent bacilli, although such carriers may develop no symptoms. Cultures should be taken from all contacts before determining quarantine in all cases of diphtheria. [E. H. R.]

10. Von Pirquet, C. E. *Allergy.*

2. Brem states some valuable conclusions from his studies of malaria in Panama. "Blackwater fever," he says, includes two types of hemoglobinuria more or less definitely associated with malaria. The two types differ in etiology and symptomatology and the indications for treatment are diametrically opposed. Type 1 is hemoglobinuria associated with pernicious malarial infections. The hemoglobinuria is probably brought about by immediate destruction of erythrocytes by enormous numbers of sporulating parasites, and the time of its appearance can generally be foretold with a fair degree of accuracy. The treatment is that of pernicious malarial fever. Type 2 is hemoglobinuria indefinitely associated with malaria and probably brought about by the solution of erythrocytes by an unknown hemolysin. It may be termed erythrolytic hemoglobinuria. In this second type quinine should never be given while hemoglobinuria is present; after the cessation of this symptom it should be given guardedly if parasites or fever persist or recur.

5. Thayer reports a case of pernicious anemia in which he observed characteristic ameboid movements in a megaloblast. Small round pseudopodia were projected, into which the colored protoplasm flowed in much the same manner seen with the ordinary intestinal amebæ. Slight changes in shape occurred at times in the nucleus. The movements of the cell were marked, strikingly like those in leucocytes, and entirely unlike the gradual changes of shape sometimes seen in red blood corpuscles in the fresh specimen. The change was so distinct that in the course of five minutes the whole picture was different. In conclusion, the writer observes that in the early stage of development represented by the megaloblast the red corpuscle is probably a cell with powers of active progression.

7. Duval and Gurd describe their researches on the pathogenicity and viability of B. lepræ and on immunity against this organism. They find that the bacilli of leprosy are capable of living and retaining their infectibility for months under adverse conditions outside the animal body; also that the bacilli can be cultivated from contaminated leprous tissue and from the nasal discharge that has been kept at room temperature for more than a year. All this shows the necessity of early diagnosis and the need of strict segregation of certain types of the disease. The animal experiments of the writers confirm the belief that the nasopharynx is the port through which the bacilli gain entrance to the body, as well as the chief source from which infection spreads. The bacilli may gain entrance through breaks in the skin without giving rise to lesions at the entrance site. The serum of patients contains antibodies, and complement is present in normal quantities. Specific amboceptors are present in comparatively large quantities, but only those combining with lipoid bodies. The authors hope to prepare a serum of sufficient antilipoid potency to be of service in the passive immunization of human cases. In the meantime they are continuing vaccine treatment and are attempting to produce an active immunity in animals.

9. Roper and Stillman made an exhaustive clinical study of the "improved" or "C" Cammidge test in which Cammidge claims, the presence or absence of pancreatitis is indicated by the examination of a single specimen. They base their conclusions on a large number of examinations in forty cases representing all types of disease. They find that the "C" reaction does not rest on a sound scientific basis. The formation of the typical crystals is due to the presence of glycuronic acid. As this substance is present in the urine of persons in normal health, and is increased in amount in many conditions in no way associated with disease of the pancreas, the demonstration of these crystals can have no diagnostic value. [L. D. C.]

15. SHEPPARD, A. *Medical Practice in Stuart Times.*

2. Russell describes extraperitoneal Cæsarian section and enumerates the advantages of this operation and the special occasions when it is indicated.

3. Brownlee briefly goes over the history of general anesthesia and of spinal anesthesia. He compares the relative advantages of the two methods from the point of view of patient and surgeon, and the after-effects of the spinal method.

4. Ryall covers the same ground, somewhat more in detail, as in the previous article, in regard to the relative advantages and disadvantages of spinal versus general anesthesia.

5. Braithwaite, in a similar way, as above, discusses the use of cocaine as a general anesthetic.

7. Fairlie has made a careful study of blood pressure in ether and in chloroform anesthesia, and the subsequent shock to the patient. From his investigations he is led to believe that in prolonged operations blood pressure is more depressed, with consequently greater shock, in ether than in chloroform anesthesia. [J. B. H.]

EDINBURGH MEDICAL JOURNAL.

FEBRUARY, 1911.

1. *MACKINTOSH, A. W., FALCONER, A. W., AND ANDERSON, A. G. *Congenital Family Cholemia.*
2. DOW, A. *Some Operative Procedures about the Knee-Joint.*
3. *LOW, C. R. *Fungous Infections of the Finger Nails.*
4. *WATSON-WEMYSS, H. L. *Erythremia; with Notes on Two Cases.*
5. MELLAND, C. H. *Some Conditions Associated with Enlargement of Lymphatic Glands.*

1. The writers report in detail on a case of this interesting condition which was very carefully worked up. The principal features were chronic icterus dating from a few weeks after birth, markedly enlarged spleen, a normal liver and very definite changes in the blood. They discuss these features at length, as well as previously reported cases. In differential diagnosis they consider splenic anemia, hypertrophic cirrhosis of the liver, syphilis, pernicious anemia, leukanemia and others. There is a complete and excellent bibliography. The article is well worth reading.

3. Low, in a paper illustrated with excellent plates, discusses the various fungous infections of the finger nails under three groups: (1) Ringworm of the nails, (2) favus of the nails, (3) a fungous infection of unknown origin. The subject is carefully and interestingly worked out.

4. Watson-Wemyss reports two cases of erythremia and discusses the general subject. He divides polycythemia into two classes, relative and absolute. The absolute he subdivides into erythrocytosis, an increase in reds, the result of a vital reaction on the part of the organism: and erythremia, excessive red blood corpuscles of unknown origin corresponding to leukemia. He subdivides cases of erythremia into further groups according to high or low blood pressure, large or small spleen, etc. The characteristics of the blood are (1) an absolute and persistent polycythemia, (2) a considerable leucocytosis, (3) a great increase in viscosity and (4) in the total volume. He discusses different theories as to the etiology of this condition: That it is (1) a primary myelopathy, (2) splenic tuberculosis, (3) diminished destructibility of the red cells, (4) diminished oxygen-carrying power. [J. B. H.]

DEUTSCHE MEDIZINISCHE WOCHENSCHRIFT. No. 8.

FEB. 23, 1911.

1. SCHULTZE, E. *The Recognition and Treatment of Multiple Sclerosis in Its Early Stages.* (*Clinical Lecture.*) (To be continued.)
2. *MÖLLERS, B. *The Type of Tubercle Bacilli in the Sputum of Consumptives.*
3. *ROTHE. *Investigations on Tuberculous Infection in Childhood.*

5. BREDOW, F. *Occurrence and Cause of Muscle Rigidity in the Upper Thoracic Region.*
6. PERCATORE. *Observations on Bronchial Asthma.*
7. ASCOLI. *Biologic Diagnosis of Anthrax by the Precipitation Method.*
8. POLLACI, G. *The Technic of Rapid Bacterial Diagnosis in Asiatic Cholera.*
9. JOANNIDES, N. Z. *The Treatment of Syphilis with Salvarsan.*
10. PLOCH, F. *Cure of an Esophageal Stricture with Fibrolysin.*
11. MÜLLER, A. *A Toxicity Experiment with Bromural.*
12. WOLFFENSTEIN, R. *Stable Hydrogen Peroxide.*
13. TRAUTMANN. *The Significance for Europe, especially Germany, of the Plague Outbreak in Manchuria.*

2. Möllers has examined the sputum of 51 cases of pulmonary tuberculosis by means of stains and animal inoculation and cultures. Practically all of the cases were of the human type and this makes 632 cases now recorded of pulmonary tuberculosis in which human type of bacilli only were found. Thus he considers that this is another proof in favor of Koch's claim that bovine tubercle bacilli play an unimportant part in human tuberculosis.

3. Rothe reports on the findings at autopsy on children in regard to tuberculosis. As a result of his study, he considers that the respiratory tract furnishes the main source of entrance for the bacilli and not the alimentary tract, as so many claim. He finds that only 1.32% of the cases were infected with the bovine type of tubercle bacilli.

4. Jacoby describes a method for producing hyperemia of the lungs by means of a chair which can be placed in all varieties of positions for a patient. His article is illustrated with pictures showing the various positions. [C. F., JR.]

BERLINER KLINISCHE WOCHENSCHRIFT. No. 9.

FEB. 27, 1911.

1. FRIEDBERGER, E., AND SCHÜTER, A. *The Acute Operative Poison (Anaphylatoxin) from Tubercle Bacilli.*
2. BAERTHLEIN. *Changing Phenomena of Growth in Strains of Cholera Organisms.*
3. *PECHSTEIN, H. *The Diagnostic Value of the Glycyltryptophan Test in Gastric Carcinoma.*
4. ROSENDORFF AND UNNA. *The Differential Diagnosis and Treatment of Diabetes Insipidus.*
5. *GUTMANN, C. *The Influence of Triple Intravenous Injection of Salvarsan on the Wassermann Reaction.*
6. FALKENSTEIN. *Serologic Observations in Regard to Gout.* (To be concluded.)
7. OHLEMANN. *The Iodine Treatment of Basedow's Disease.*
8. GORDON, O. *The Albumose-Free Tuberculin Endotin and the Tuberculin Local Reaction.*
9. CRONQUIST, C. *Brief Communication on "Kleino" Capsules, a New Drug for Internal Use in the Treatment of Gonorrhea.*
10. LEWANDOWSKI, A. *New Problems in the Hygiene of Youth.*
11. POSNER, C. *The Pathology and Therapy of Hydrocele.*

3. In spite of the favorable results obtained by Neubauer and Fischer with the glycotryptophan test for gastric carcinoma, Pechstein finds that it can by no means be depended upon. Not only is the test negative in cases proved later to be carcinoma by operation or autopsy, but it is occasionally positive in cases where carcinoma is absent.

5. Gutmann advises an intravenous injection of "606" given three times with a fairly long interval between each injection. He reached this conclusion by making careful observations with the Wassermann reaction as a guide and he feels that this method of using the drug will lead to the best results. [J. L. H.]

## Obituary.

### THEODOR ESCHERICH, M.D.

DR. THEODOR ESCHERICH, who died of apoplexy on Feb. 15, at Vienna, was born at Ansbach, in Bavaria, on Nov. 29, 1857. He was the son of a physician and received his academic and medical education at the universities of Strassburg, Kiel, Berlin, Würzburg and München. In 1882 he entered the medical clinic at Würzburg, then under the direction of Dr. Karl Gerhardt. Here Escherich in time became first assistant, and subsequently served in hospitals at Paris and Vienna. Determining on pediatrics as his specialty, he published in 1886 his monograph on "The Intestinal Bacteria of the Infant and their Relations to the Physiology of Digestion." He continued till 1890 as an assistant in v. Ranke's clinic, pursuing during this time the researches which led him to the development of the volumetric system of artificial infant feeding. In 1890 he was called to succeed v. Jaksch as professor of pediatrics at the University of Graz. Here he continued his studies in infant feeding, and became interested in the serologic investigations associated with the discovery of diphtheria antitoxin by Behring. In 1894 he declined a call to succeed Heubner at Leipzig, but in 1902 accepted the professorship left vacant at Vienna by the death of Widerhofer. Here, at the St. Anna Hospital for Children, he passed his richest years of teaching, research, practice and publication. He was a contributor to numerous medical periodicals, a member of many learned societies, and was known as a pediatric consultant throughout Europe. His professional reputation was international. His energy for work was tremendous, and his disposition strenuous and masterful. He is described as impulsive, uncommonly strict,

strong-willed, faithful, severe with himself but kindly towards others. That the children, his patients, loved him, is evidence that he loved them and, therefore, had a good heart. His career is an admirable example of the life of the German university physician, scientist and professor.

## Miscellany.

### DR. CANNON AND THE ANTI-VIVISECTIONISTS.

IN the issue of the JOURNAL for March 16, we commented editorially on the recent anti-vivisection exhibit in Boston. The following letter on the same subject from Dr. W. B. Cannon to the public press on March 24 deserves reprinting in full for its efficient and authoritative exposition of some of the fallacies and misrepresentations of the anti-vivisection agitation.

"An exhibit purporting to represent the methods of animal experimentation was displayed last week in this city and was extensively noticed in some of the daily papers. A clear disclosure of the morals of organizations which claim the position of moral leadership was the real import of the exhibit. Lest this aspect be overlooked, I wish to call attention to it.

"In the center of the room was a placard on which was described the 'poisoning' of insane patients by Dr. H. J. Berkley. He was treating his patients with minimum doses of thyroid gland. 'Two patients became frenzied, and of these, one died before the excitement had subsided' — so said the placard. In the original account the sentence is completed by the words, 'the immediate cause of the exitus being acute disseminated tuberculosis.' This crafty perversion was exposed ten years ago by Dr. W. W. Keen (Jour. Am. Med. Asso., Feb. 23, 1901); no correction has yet appeared in anti-vivisection writings.

"Another placard presented statistics intended to indicate that mortality from meningitis has increased in New York City since the anti-meningitis serum was discovered. The misleading confusion, in these statistics, of epidemic meningitis, which the serum cures, with other forms, which are as yet incurable, was clearly pointed out last year by Dr. C. H. Dunn, of Boston (Life, May 5, 1910). The anti-vivisectionists have persisted in misstating the facts.

"Dogs — miserable, wasted creatures — were represented in two drawings of Pawlow's 'Scientific Torture Chamber.' Any one who has read Pawlow's classic work on the digestive glands (for which he received a Nobel prize in medicine) knows how strongly he insisted that the prime conditions for the action of these glands are freedom from distress and the satisfactions of appetite. The drawings in the anti-vivisection exhibit represented the animals quite falsely, as is readily proved by photographs of the dogs and the testimony of persons who have visited Pawlow's laboratory.

"A large painting hung on the wall pictured a medical lecture. 'Now, gentlemen,' the professor remarks, 'having shown the extreme sensitiveness of these organs, I will perform some amusing experiments with the brain and the nerves of the eye to-morrow morning, provided, of course that the animal is still alive.' As publicly stated last year (North American Review, June, 1910), medical schools throughout the entire country have adopted humane regulations safeguarding against pain and discomfort the animals used for experimental purposes. Both the picture and the words attributed to the professor are a wicked travesty of the truth.

"Disposed on tables were pamphlets and leaflets which visitors were urged to take. These circulars contain garbled statements, misleading quotations, and reiterated falsehoods, the character of which has been often pointed out. (See 'Some Characteristics of Anti-Vivisection Literature,' published by the American Medical Association.) Several of the circulars report opinions of medical men in opposition to vivisection. Sir Charles Bell is quoted — he died in 1842. Dr. John Elliotson, a mesmerist, is quoted — he was born in 1791. Dr. Charles Clay, 'collector of fossils,' was born in 1801. Dr. Garth Wilkinson, poet and mystic, born ninety-nine years ago, held an honorary M.D. degree. In the antivivisection circulars no reference is made to the lifetime of these physicians — an important consideration when we remember that the experimental method has been used in medicine mainly since ether anesthesia was discovered (1846), and that the greatest triumphs have come since 1880. Among the living physicians, Sir Frederick Treves is quoted; nine years have passed since he first complained (London *Times*, April 18, 1902) of the adroit misuse of his remarks by the anti-vivisectionists — but of what avail! Dr. Arabella Kenealy, who is hostile, sets herself down in 'Who's Who' as a novelist. Dr. W. Gordon-Stables describes himself as professional writer and author of one hundred and thirty-six books with serial novels. Dr. E. Berdoe (74) reports himself as a writer, author of many volumes on Browning; Dr. Josiah Oldfield is a fruitarian lawyer; Dr. J. D. Buck (72), a theosophical propagandist and writer on theosophy; Dr. Stephen Townsend, a novelist and actor on the stage for years, playing prominent rôles in 'Sowing the Wind,' 'Slaves of the Ring,' 'Black Tulip' and other plays. Most of these 'doctors' are quoted as 'men of greatest eminence among the vast number of physicians and surgeons who have opposed vivisection'!

"The description of experiments on animals, with no reference whatever to the motives for experimentation, or to the precautions against infliction of pain, or to the beneficent results of medical research, must lead otherwise uninformed persons to the conclusion that the men engaged in advancing medicine are moral perverts delighting in agony and blood. No more cruel treatment of high-minded men was ever devised than that.

"The instances of deception which I have mentioned should be regarded merely as examples; many more of like nature could be mentioned. Enough has been stated, however, to show that the anti-vivisectionists have been exhibiting themselves and their methods rather than the procedures of the laboratories. Their persistent appeals, through deceit and innuendo, to the finest feelings in man, for the purpose of rousing hostility towards studies immeasurably important to human welfare, is a matter of serious concern. If medical investigation is not to be severely hampered in this country, such attempts as the anti-vivisectionists have made to misrepresent laboratory methods and to appeal to ignorance and passion must not pass unheeded."

Dr. Cannon is a member of the committee of the American Medical Association on the restriction of animal experimentation, and his statements are those of an expert who has made a special study of the problem in the defense of legitimate medical research against legislative encroachment and the interference of misguided enthusiasts.

## FATALITIES FROM PLAGUE IN THE ORIENT.

REPORTS from various sources during the past week indicate a continued decrease in the Oriental epidemic of bubonic plague. More authentic data are now at hand regarding the actual number of fatalities from the disease. Report from the British India Office at London states that during the month of February there were 88,498 deaths of plague in India. A report by the United States consul at Harbin estimates that one fifth of the entire population of northern Manchuria has perished. There are said to have been 3,402 deaths at Fuchiatien and 831 in Harbin. Three hundred Chinese and eighteen European physicians are reported to have died. Intelligence from China by way of Seattle, Wash., states that there have been over 2,300 deaths from plague in and about Chang Chuen during the past three weeks. Report is said to have been received on March 16, at Washington, D. C., from the United States consul at Port au Spain, Trinidad, that a single case of the disease has recently occurred in that island. Report from Pekin announces that the International Plague Conference will assemble on April 3 at Mukden for a fortnight's session. Dr. Strong will be the United States representative at this conference, Dr. Brocquet the French delegate, and Drs. Farrar and Petrie the representatives from England.

## RECORD OF MORTALITY

## SOCIETY NOTICE.

AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION. — The fourteenth annual meeting of this society will be held at the Bellevue-Stratford, Philadelphia, April 19 and 20, 1911.

## RECENT DEATHS.

ANNE SOPHIA KENNEY PATCH-LINDQUIST, M.D., M.M.S.S., died in Boston, March 18, 1911, aged forty-seven years. Dr. Lindquist was born at Milton, N. H. She received the degree of M.D. from Tufts in 1896, and had practiced medicine in Boston since that time. She is survived by her husband and by one son.

DR. EDWARD WALTER BRANIGAN, who died of heart disease on March 23 in Cambridge, Mass., was born at Salem, Mass., in 1858. After a preliminary education in the public schools of that city, he went to California, where he was for several years engaged in newspaper work. Returning to Boston in 1878, he began the study of dentistry, and in 1882 graduated from the Boston Dental School. Since that time he had practiced his profession in Boston. For some years he had been professor of clinical dentistry at the Tufts Dental School, and for the past few months its acting dean. He was a trustee of the Forsyth Dental Infirmary, and had been actively interested in preparing the plans for its projected building. He was a member and former president of the National Association of Dental Faculties, and a member of the Massachusetts Dental Society. He is survived by one son, a practicing dentist at Groton, Mass.

DR. EDWARD FISKE ASHLEY, one of the bacteriologists at the Quarantine Hospital, New York, died at the post of duty, on March 21, from malignant cerebrospinal fever. He had performed the autopsies in fatal cases of this disease from the steamship *Martha Washington*, and also made bacteriological tests in the laboratory with specimens from living patients. The Flexner serum was promptly resorted to, but he died on the third day of the attack. Dr. Ashley, who was from Waterbury, Conn., was graduated from the Yale Medical School in 1900. He had been in Dr. Doty's laboratory service only during the past year.

DR. RAYMOND W. BROWN, house physician of the Hudson Street Hospital, New York, died on March 24, from cerebrospinal fever, after an illness of only eighteen hours. It is stated that he had recently treated some Greek immigrants and that it was probably from one of these that he contracted the disease. In his case, like that of Dr. E. F. Ashley, the Flexner serum proved unavailing. Dr. Brown was a native of Cobleskill, N. Y., and was graduated from the medical department of the University of Pennsylvania in 1908. Before entering the Hudson Street Hospital service he was an interne at the Nursery and Child's Hospital, New York.

DR. JAMES WILLIAM DODD HANCOCK, of Brooklyn, N. Y., died on March 22, from injuries received in an automobile accident five days previously. He was a native of New York City and forty years of age and was graduated from the Long Island College Hospital, Brooklyn, in 1896. At the time of his death he was associate attending surgeon to the Williamsburgh Hospital, Ear, Nose and Throat Department.

## BOOKS AND PAMPHLETS RECEIVED.

Report of the Commission to Investigate the Question of the Increase of Criminals, Mental Defectives, Epileptics and Degenerates. January, 1911.

Das Radium in der Biologie und Medizin von Prof. E. S. London. Leipzig, 1911.

Prevention of Hemorrhage in Pulmonary Tuberculosis by the Administration of Autogenous Vaccines. By Roswell T. Pettit, B.S. Ottawa, Ill. Reprint.

Examination of Prof. Irving Fisher's Report on National Vitality. By Lawrence Irwell. Reprint.

The Modern Materia Medica. Second edition. The Druggist's Circular. New York, 1910.

Diseases of the Eye. By Dr. Curt Adam. New York: Rebman Co.

Atlas of Microscopic Diagnosis in Gynecology. By Dr. Rudolph Jolly. New York, N. Y.: Rebman Co.

Tuberculose oculaire et serum anti-tuberculeux du docteur Marmorek par le docteur Arnold E. Verrey. Reprint.

Differential Diagnosis of Alcoholic Coma from Other Forms of Coma, with Especial Reference to the Care of Unknown Persons Found by the Police on the Streets in a Comatose or Semi-Comatose Condition. By Lewis D. Mason, M.D. Reprint.

Transactions of the American Surgical Association. Vol. 28. Archibald MacLaren, M.D., editor. 1910.

Golden Rules of Diagnosis and Treatment of Disease. By Henry A. Cables, B.S., M.D. C. V. Mosby Co. 1911.

Transactions of the American Urological Association. Ninth annual meeting at St. Louis, Mo., June 6 and 7, 1910.

## Original Articles.

# SOME OBSERVATIONS ON THE DISORDERS OF THE STOMACH AND DUODENUM WITH ESPECIAL REFERENCE TO ULCERS.*

BY WILLIAM J. MAYO, M.D., ROCHESTER, MINN.

In deriving the name "abdomen" from the Latin word *abdere*, meaning to conceal, an early ancestor had a most prophetic vision. The history of disorders of the abdomen is a compilation of strange hypotheses, curious fancies, and absurd statements; indicating a woeful lack of knowledge, and that concealment of its true pathology was fairly complete.

Until surgery came to our aid, we had no means of directly inspecting the abdominal contents during life, and this led to too great dependence upon clinical data derived from indirect methods of examination, and the result of post-mortem investigations. But since we have been able, through surgical means, to bring the abdominal organs and their diseases to the light of day for examination, order has come out of chaos and facts have replaced supposition and imagination.

Ocular inspection has always been necessary to dispel mysteries and develop the truth. The eye, or the eye aided by the lens and the microscope, brings out facts which would otherwise remain in obscurity.

The post-mortem has permitted such direct inspection; but not in the living body, or under normal conditions. The post-mortem showed the condition which caused death, but in chronic disease this was seldom the pathologic condition which existed during life and which gave rise to the symptoms, but rather the result of terminal infections and secondary complications which so obscured the original disease that it paled into insignificance and was lost sight of in the gross pathology immediately present.

No truer remark has ever been made in this connection than "Few people with chronic disease die from the disease which was present during life."

Post-mortem pathology replaced with solid facts the preceding era of clinical observation. It is the foundation of medicine and it introduced a school of medicine which for the first time could be called scientific. During this magnificent period of pathologic research some of the greatest discoveries of modern medicine have been made. This period has given us the name of Virchow, Koch and a host of workers in minute pathology and the microbic origin of disease. The name of Reginald Fitz will be remembered long after the rest of us are forgotten for his three remarkable contributions to the pathology of the abdomen, i. e., Meckel's and other diverticula, the appendix and the pancreas.

We are now opening out into a new era, that of physiological research and the study of diseased processes in the living, during the curable stage of the disease.

The pathologic era led to pessimism in medicine because it dealt with terminal conditions, just as the preceding period of clinical observation led to empiricism in medicine and left behind it a legacy of "pathies" and "isms" which still exist.

Direct inspection has led to great discoveries in other fields, such as the urinary bladder. The cystoscope, ureteral catheter and the x-ray have developed the pathology of this viscus to a remarkable degree, and its story, therefore, has necessarily been rewritten.

During the transition period the bladder was supposed to be diseased with extraordinary frequency. It is now known to be the least often diseased of any organ of its size and importance in the abdomen.

Primary tuberculosis of the bladder is one of the rarest pathologic conditions. In 99% of women and 86% of men, tuberculosis of the bladder is secondary to tuberculosis of the kidney, and the remaining 14% in men are due to tuberculous disease of the epididymis, vas deferens, seminal vesicles and prostate, yet the symptoms are those of intractible cystitis for which the bladder has been diligently and unavailingly treated for years.

The male bladder was supposed to be diseased more frequently than that of the female, because of some peculiar predisposition which it had to disease; but we now know that it was not "predisposition," but the result of prostatic hypertrophy, posterior urethritis and diseases of the seminal vesicles, to which the male bladder owed this marked liability.

Unfortunately, the gastroscope has no such record of achievement as the cystoscope, and ocular inspection through the abdominal incision has been necessary to obtain exact knowledge of the pathology of the stomach. Like the urinary bladder, the stomach is rarely diseased of itself, although giving rise to more complaints, and, I may say, receiving more unnecessary treatment, than any other organ in the body. Clinical observation had availed but little and the post-mortem, with few exceptions, had failed to establish the pathology of the living.

Through direct operative inspection, Tait[1] exploded the clinical theory of pelvic cellulitis, showing that the symptoms were due to suppurative salpingitis; and he also demonstrated that so-called "broad ligament hematoceles" were, in truth, extra-uterine pregnancies.

A great number of supposititious diseases in the abdomen have been shown, by operative inspection, to be the result of appendiceal infections, and gallstones have been shown not "innocent." In the same way the accumulated rubbish of supposititious diseases of the stomach has gone to the scientific garbage can, as surgical examinations have worked from the lower to the upper abdomen.

The functions of the stomach may be divided into two groups, — the mechanical and the chemical. Of these the mechanical is by far the most important, any interference in the way of ob-

* Read before the Section on Surgery, Boston Medical Library Association, Jan. 18, 1911.

struction to the onward progress of food promptly giving rise to symptoms. Changed chemical conditions which follow partial gastrectomy, or which follow gastrojejunostomy where the gastric secretions are seriously interfered with, apparently do not give rise to serious difficulty so far as the health and comfort of the patient is concerned; and the attempt to built up a pathology for the stomach based upon chemical analyses of the gastric secretions has proved a lamentable failure.

Pawlow [2] and Starling [3] have shown that gastric secretions are readily changed by the character of the food, and not only is this true, but in many non-gastric disorders the secretions of the stomach are changed and a large number of general diseases exhibit gastric phenomena of such severity as to overshadow for a time the originating disease.

I am sure that in times gone by all physicians have treated the stomach because of aggravated gastric distress which depended upon cardiac or renal insufficiency. Gastric symptoms sometimes antedate the usual signs of pulmonary tuberculosis. Arterioesclerosis is commonly attended by gastric disturbances; a high percentage of the cases of pernicious anemia are believed to be the result of some stomach disease and quite often, on account of the lack of acids, thought to be cancer.

Diseases of the nervous system often give rise to marked gastric distress, and every year we see a few cases of unavailing surgical decorations on the abdomen for the gastric crises of tabes.

Eliminate from the stomach all of the complaints which are the result of general diseases, and we eliminate about one third of all the serious gastric disturbances which one is called upon to treat, and for which, through lack of true knowledge, treatment has been freely offered in the past.

The three closely associated conditions, — atonic dilatation, gastroptosis and gastric neurosis, — give rise to much gastric distress. However, the stomach is not the offender, but rather are the symptoms due to an unstable nervous system and to congenital physical defects. Admitting that food leaving the stomach is delayed in atonic dilatation, the delay does not depend upon mechanical obstruction. The prolapsed stomach is often shown, by bismuth and x-ray, to be more nearly pelvic than upper abdominal in location, yet the gastroptosis is usually a part of a general enteroptosis and does not give rise to mechanical conditions so far as the progress of food is concerned.

Among the protean manifestations of neurasthenia, stomach complaint is the most common. This group of cases has given rise to many fads in medicine. Eminent gentlemen have asserted that no case of gastric ulcer should be operated upon until the patient had had his eyestrain corrected. Authorities stated that gastric ulcer was more common in women than in men, and that distress in ulcer followed at once upon eating. Osteopathy, Christian Science, walking barefoot through the grass, Lydia Pinkham's remedies, and Pierce's, as well as our own favorite prescriptions, and that time-honored fake, that loaded-dice and shell-game of the medical profession, "electricity," all achieved about the same results in the treatment of these conditions.

Then surgery entered the field with enthusiasm. Some of these poor patients had gastrojejunostomy and other stomach operations performed for supposititious ulcers, much to the discontent of the patient, the physician and the surgeon; and in the records of these cases "failure of operation to cure the ulcer" was put down when it should have been recorded, "unnecessary surgical interference."

When we eliminate atonic dilatation, prolapse of the stomach, gastric neurosis, etc., another one third of stomach complaints have been disposed of. To treat these patients successfully we would have to begin four generations back; and even medicine has its limitations.

The control of the pyloric apparatus is not vested in the stomach itself, but in the duodenum, and, under certain circumstances, in the derivatives of the midgut. This has been shown by Cannon,[4] Pawlow, and Starling. In experimental gunshot wounds through the intestine, the pylorus will close automatically for a number of hours; an attempt on Nature's part to prevent food from coming down into the injured area.

In acute appendicitis, we have nausea, vomiting and pain all over the abdomen some hours before there are localized symptoms in the region of the appendix; just as in strangulated hernia, nausea and vomiting and symptoms of acute indigestion precede local evidence of the disease at the hernial site.

In some cases of chronic appendicitis (especially those appendices which contain fecal stones); in tuberculosis of the ileocecal coil, intestinal tumor, chronic intussusception, gallstone disease, etc., marked disturbances of the stomach are sometimes the chief or only symptoms of the disease. These patients go on for years, complaining and receiving treatment for indigestion and dyspepsia, although the stomach is merely acting as a mouthpiece to call attention to the disturbance. Treating the stomach under such circumstances is about as sensible as it would be to deluge with water a fire-alarm box because it was indicating the presence of fire in some other locality.

Maintenance of the body is a primitive function and it existed before there was a nervous system. The control of the primitive intestinal tract is dependent upon chemistry, "internal secretions," which Starling calls "hormones." These internal secretions are correlated through the blood stream and the sympathetic nervous system upon which the internal secretions act. Organs of more powerful internal secretions, such as the adrenals and the hypophysis, are structurally associated with the sympathetic nervous system like the mechanical piano-player, where the "player" is built inside the piano itself instead of being an attachment.

The fundus of the stomach was a much later addition, coming after the cerebrospinal nervous system had developed; it is, therefore, more or less under conscious control. The stomach is endowed with storage function for the convenience of rapidly placing into it a quantity of material for the slower work of digestion and assimilation, — work which must be done by the organs that have their control in the internal secretions and which compose the territory between the beginning of the antrum of the stomach and the splenic flexure of the colon.

Disturbance in the assimilative tract brings about a closure of the pylorus called "pylorospasm," which delays the food from leaving the stomach; the result is indigestion, dyspepsia and gastric distress. We have no conscious knowledge of the organs directly involved except as we receive it through the stomach, just as we have no conscious knowledge of the kidney function except as we receive it through the urinary bladder. And herein lies the explanation of the stomach complaints, of gallstones, appendicitis and other diseases of the intestinal tract.

Eliminate all of the disorders of the stomach which arise from diseases of the digestive tract outside the stomach, and we will eliminate about 20% or more of the so-called "gastric diseases" and come down to a meager 10% in which there is actual demonstrable disease. I believe that we are well within the truth in saying that 90% of supposed diseases of the stomach are not entities, but rather groups of symptoms masquerading as diseases, and named accordingly.

This lengthy preamble seems almost out of place in a discussion of ulcer of the stomach and duodenum, but it has been made necessary by the misconceptions and errors which only of late have been brought to light under direct inspection of diseases of the stomach in the living.

Twenty-five years ago we were taught that simple peptic ulcer was a disease of the stomach more common in women, and that it was usually multiple. It was supposed that the duodenum was very rarely affected. Later investigation has shown that the ulcers referred to were a form of acute ulcer and that they were especially frequent in the overworked, underfed and badly nourished female. Modern social conditions have, however, changed greatly for the better, and this type of acute ulcer, with a high percentage of mortality so familiar to the older pathologist, is now rarely seen.

Acute ulcers are usually toxic, and the patient either dies or recovers within two or three weeks; they are often multiple, sometimes with a large number of perforations at one time. Bordon[5] demonstrated that acute ulcers of this type could be produced experimentally by making an extract of the stomach scrapings of a normal guinea-pig's stomach and injecting it into the normal rabbit. In a very beautiful piece of work he showed that these ulcerations were due to self-digestion; the gastrotoxic extract had in some way taken away from the stomach of the second animal the ability to protect itself against auto-digestion. He could prevent this action by keeping an alkaline solution in sufficient quantity in the stomach to neutralise the gastric juice. Turck[6] showed that, by feeding animals a large quantity of filth and colon bacteria, he could produce multiple acute ulcers in the experimented animal.

In this manner we can explain the acute multiple ulcers of the chlorotic female, and the hemorrhagic erosions which cause severe hemorrhage in cirrhosis of the liver and some blood diseases. But neither experimentally nor clinically have these acute ulcers been found to be responsible for the chronic calloused ulcer of the stomach and duodenum.

The whole question of chronic calloused ulcer must be reconsidered. Up to the present time the statistics of John Brinton,[7] which were compiled in the early sixties, and those of Welch,[8] compiled in 1885, have been accepted as definitely establishing certain facts. The work done by these two men is a splendid example of pathologic research, and a model of their time. The actual pathologic examinations upon which these statistics were based, however, were not made by these eminent authorities, but were merely compiled by them. Welch's statistics covered the findings from the autopsy material from ten large German clinics during a still earlier period some years prior to the publication of the paper. These statistics represented what was well known at that time, but by no stretch of imagination can we consider them as representing the knowledge of to-day any more than we can settle other mooted questions in medical progress by data accumulated twenty-five to sixty years ago. For example, since the compilation of these two monographs, the facts as regards the germ origin of disease have been discovered, and, in truth, the whole aspect of medical science has changed.

Actual inspection through exploratory incision shows conclusively that both duodenal and gastric ulcers are more often found in the male sex, that chronic duodenal ulcer is more common than gastric, and, in the large majority of cases, only a single ulcer is present.

For purposes of comparison we have taken 1,000 cases operated upon at St. Mary's Hospital for gastric and duodenal ulcers, which includes all of the cases operated upon up to Jan. 17, 1911. Of these, 745, or 74½%, were males, and 255, or 25½%, were females.

Previous to June 1, 1906, the differentiation between gastric and duodenal ulcers was not well established and many ulcers which were duodenal in origin, but which extended up to the pylorus, were supposed to be gastric. However, since June 1, 1906, 621 authentic cases of gastric and duodenal ulcers have been operated upon (Jan. 17, 1911), of which 201 (32½%) were gastric and 401 (64½%) were duodenal, and 19 (3%) had one or more ulcers of both the stomach and duodenum. Including all the types of operations, — resections, excisions, gastrojejunostomies, etc., — there was an operative mortality of 15, 2½%. The mortality figures include all the cases operated

upon who died in the hospital without regard to cause of death or length of time after operation.

The terminal three fourths of an inch of the pyloric end of the stomach, known as the "pyloric canal of Jonnesco," [9] is a part of the pyloric apparatus. It is usually closed and is not subjected to the traumatism nor is it exposed to the action of the gastric secretions to the same extent as the pyloric antrum. It follows, therefore, that pyloric ulcers are rare. A differential diagnosis between duodenal and pyloric ulcers may be difficult, but if the pyloric vein [10] be sought, the relation of the ulcer to the pylorus will be readily ascertained. In this connection I would say that traction made upon the upper duodenum in drawing it up into view will sometimes produce temporary avascularization just below the pylorus, and the small bleached spot, the "anemic spot," [11] may be mistaken for ulcer.

More than 90% of ulcers of the stomach are situated along the lesser curvature. The ulceration is sometimes more extensive on the posterior wall, less often on the anterior wall. The induration often extends from the ulcer downward upon the anterior and posterior walls like saddle-bags and, therefore, is termed "saddle ulcer." [12]

Ulcers not along the lesser curvature are more frequent on the posterior than the anterior wall of the stomach. While the induration may be very considerable in extent, the rule is that the actual ulcer is not larger than the end of a slate pencil to that of a nickel, averaging about the size of the end of a lead pencil. Most ulcers which are larger than a silver twenty-five-cent piece are undergoing malignant degeneration. At operation the surgeon may be inclined to believe, on account of the induration and extent of scar tissue, that the size of the ulcer is much greater than it is. It is rather amusing to see in bismuth and x-ray plates supposed to show ulcers of the stomach and duodenum, shadows of a size and character never seen in the living subject.

Less than 6% of the ulcers which we see are multiple, although there is sometimes an erosion on the opposite wall to the ulcer representing the point of contact, which we call "contact ulcer." [13]

Ulcers both of the stomach and duodenum often perforate, but these perforations are rarely into the free peritoneal cavity. In our entire series we have only had thirty-one such cases, while nearly one third had undergone chronic perforation, protected by adhesions to the neighboring organs. The posterior wall of the stomach, the lesser curvature and the duodenum are especially favorable in this respect, in that they are in close proximity to neighboring structures. Free perforation usually takes place along the anterior wall where there is less protection. Subacute perforation with formation of secondary abscesses, subdiaphragmatic or otherwise, are the results of escaping fluids from a perforating ulcer which has been imperfectly closed by advance adhesions.

The larger number of acute perforations are perforations through chronic ulcers. The fluids gravitate downward, and in duodenal ulcer a considerable percentage of our earlier cases upon which we operated were done with the pre-operative diagnosis of perforated appendix. The condition of the appendix did not justify this conclusion, and led to further search until the cause was found in the duodenum.

The diagnosis of gastric and duodenal ulcers is usually not difficult, and the differential diagnosis between a gastric and a duodenal ulcer can usually be established, but it cannot always be done, nor is it essential that it should be. The duodenum above the common duct is a part of the stomach and not a part of the small intestine. It is derived from the primitive foregut, the same as the stomach. Its mucous membrane is thin and granular, it has no valvulæ conniventes and is entirely unlike the small intestine. Apparently it is a vestibule to the small intestinal area, and its embryology, its function and its diseases are those of the stomach. I believe that it would not be far out of the way if we classified it as part of the stomach, dividing the stomach into the fundus, antrum, pyloric canal and proximal duodenum.

In the early stages of gastric and duodenal ulcer, hyperacidity and hypersecretion are prominent features, and the pain is usually in the "pit" of the stomach. In some cases of duodenal ulcer the pain passes to the right, and in some gastric ulcers to the left. The location of the pain, however, is often misleading in this respect. Hyperacidity is often not as well marked in gastric ulcer as in duodenal ulcer, and, generally speaking, in both gastric and duodenal ulcers hypersecretion is more persistent than hyperacidity. The pain in duodenal and gastric ulcers in the vicinity of the pylorus usually comes on from one to three hours after meals. In gastric ulcers of the body of the stomach, the pain comes on earlier following the meal, and while duodenal and antral ulcers are almost regularly relieved by taking food, in ulcers of the body of the stomach, food sometimes gives rise to pain. The belching up of sour fluids from the empty stomach has a very deleterious effect upon the teeth, and often these patients will have the incisor teeth of the upper jaw dissolved away nearly to the gum. Hunger pain and food relief are very typical of ulcer. The patient who goes to bed at night with a glass of milk and a cookie or soda-water, because he expects to wake up in the night with a peculiar gnawing pain in the stomach, sometimes raising up a mouthful of bitter, sour, burning fluid, will almost regularly be found to have ulcer and usually ulcer of the duodenum. It is curious to note in some cases the regularity with which the pain appears in the night. For months at a time it comes on at almost identically the same hour.

As to hemorrhage: Not over 30% of our cases give a clear history of hemorrhage, although by asking leading questions regarding black stools, etc., nearly 70% of histories of hemorrhage can be procured. Many of them, however, leave a

lingering doubt in one's mind as to their validity. Of all the prominent signs and symptoms of ulcer, hemorrhage is the least valuable, and unless the hemorrhage is preceded and followed by the usual evidences of ulcer, it is probably not due to chronic ulcer, but belongs to that queer group of toxic erosions which I have already mentioned. If there is doubt in our minds as to the cause of hemorrhage which we see coming from the stomach, what must our attitude be toward the so-called "occult blood" in the stool. If found, it is merely up to us to guess where it came from. If it is corroborated by other evidences of a substantial nature, it has value, but of itself it means little.

It is always advisable to examine the gross specimen brought up by the stomach tube from the fasting stomach. The yellowish, sour, pungent fluids, the result of hypersecretion and hyperacidity, are in marked contrast to the dirty, sickish, coffee-ground material so often found in cancer.

Laboratory diagnoses based upon the analyses of the gastric contents are valuable but they are not the controlling factors in the diagnosis and must be corroborated by other signs and symptoms.

In the later stages of the disease, obstruction supervenes, and the finding of food remnants eight to ten or twelve hours after meals, or the habitual use of the stomach tube to remove these undigested particles, is not only most important in diagnosis, but, I believe, furnishes a surgical indication which should not be ignored.

Gastric and duodenal ulcers may exist for years. The disease usually begins in the young adult who develops a history of stomach trouble marked by bitter, sour, acid belching and regurgitation coming on from one to three hours after meals and relieved by taking food. With or without treatment the symptoms will abate and, in the early history, will disappear for months or years at a time, leading to the delusion that the ulcer is cured. These "spells" recur at closer and closer intervals until, in the later stages, obstruction supervenes and, as the acids then diminish and blood is sometimes present, the patient is thought to have cancer and he will turn his face to the wall, fairly content to die in order to escape his punishment.

Every year we operate upon a number of patients with obstruction who are in a most advanced state of emaciation and malnutrition due to simple ulcer, but supposed to have malignant disease. The average duration of symptoms in the cases we have operated upon has been twelve years, seven months and some odd days. Certainly this does not appear to be a hasty resort to operative treatment.

*Surgical treatment of gastric and duodenal ulcer.* When shall we operate upon gastric and duodenal ulcer? I used to say "after nine complete and permanent medical cures." Do the chronic calloused ulcers get well under medical treatment? I do not know. However, we have operated upon a great number of cases when the symptoms were in abeyance and it might be thought that the patient was cured, but I have never seen one in which there was definite closure of the ulcer. It is the old story of appendicitis and gallstones over again. The symptoms are intermittent, but the cause remains until it is removed.

As to acute ulcer and the early stages of other ulcers: It is entirely probable that definite healing takes place, and personally I have no doubt that a very high percentage of the cases recover without operation, but I have very grave doubts as to the permanent, spontaneous cure of *chronic* calloused ulcer. In the large majority of cases, if such cure could be brought about, the cicatrix produced in healing would result in obstructive phenomona and the later stage would be worse than the first.

It is in these cases of old chronic obstruction, in which the obstruction has eliminated the hyperacidity and, for that matter, nearly abolished the functions of the stomach, that I have seen the closest resemblance to definite healing.

Posterior gastrojejunostomy is efficient in duodenal ulcer. Occasionally a duodenal ulcer can be excised, or the excision of such an ulcer, combined with pyloroplasty, or the Finney operation,[14] is possible. The ulcer can usually be enfolded as recommended by Moynihan,[15] using two or three mattress sutures of linen. As to gastric ulcers, I believe that they should always be excised if possible. Wilson and MacCarty[16] found that 71% of over 300 of our resections of the stomach for cancer showed that the cancer had begun in ulcer, a conclusive opinion which can only be derived from surgical specimens during the curable period. An opinion based upon post-mortem findings would, of course, be quite valueless on account of the extent of the disease.

Keen[17] and Bloodgood[18] state that no case of carcinoma of the skin has been reported which did not begin in some pre-existing lesion, e. g., moles, warts, heat or sun irritation, syphilitic or tuberculous lesions, or the result of chemicals, traumatism, etc. We are just beginning to find out that carcinoma of the internal epithelial surfaces of the body presents the same condition of pre-cancerous lesions, of which ulcer of the stomach is one.

In excising an ulcer of the stomach, gastrojejunostomy is usually necessary in addition because the interference with gastric motility may be sufficient to prevent a complete cure of the patient.

## DUODENAL ULCER.*

BY FRANKLIN W. WHITE, M.D.,

*Instructor in Clinical Medicine, Harvard University; Second Assistant Visiting Physician, Boston City Hospital.*

I AM glad to have the opportunity to say something about duodenal ulcer, for I consider it a "coming disease," something like appendicitis twenty or thirty years ago. The diagnosis will be more frequently made and the condition will be better treated.

Much new information about chronic duodenal ulcer has accumulated in the last few years as a result of the activity of surgeons, especially the Mayos, Moynihan, Robson, Deaver, Codman and Hall, and we must revise many of our ideas about the frequency, the pathology, the diagnosis and the treatment of this condition. We emphasize recent surgical statistics because the diagnosis is verified by operation, and shall take up the new things the surgeons have told us rather than attempt any complete review of the subject.

We must remember that earlier statistics about gastric as contrasted with duodenal ulcer have relatively little value because the cases were not properly separated. We must also remember that the surgeons in the past have seen only the severest cases and that surgical statistics deal wholly with *chronic* ulcer.

In looking over reports we must remember that the artificial distribution of ulcer and ulcer-like cases in our large hospitals is responsible for some confusion of ideas about the class as a whole. In the medical dispensary we find the simple hyperacidities; in the medical wards, a group of ulcer cases, largely acute, such as Greenough and Joslin reported ten years ago, 80% women, at the age of twenty-five, four fifths of whom had vomited blood; and in the surgical wards the severe chronic ulcer cases, two thirds or three fourths men, the perforations, pyloric obstructions, etc. No single group represents the whole field.

To avoid confusion, we shall say little about cases with marked pyloric obstruction, which have a distinct set of signs and symptoms. We need a clear picture of the earlier symptoms in simple duodenal ulcer to aid us in making an earlier diagnosis before serious complications occur.

*Frequency.* — It is evidently not a rare disease, but, like appendicitis in the early days, many cases are seen and not recognized. The proportion of duodenal to gastric ulcers is evidently far greater than was formerly supposed. The old ratio of 1 to 12 will have to be revised.

The number of duodenal ulcers is so great in recent reports that we are tempted to ask if the pylorus has not moved. The secret is that many have been overlooked in past years, or confused with other lesions. The classical cases of duodenal ulcer with severe pain late after meals and gross blood in the stools are only a small per cent of the whole. Many are entirely latent or have perforation for the first symptom. Many perforating cases are confused with appendicitis before operation, and some afterwards; many are confused with gastric ulcer, not only in the office, but in the operating room, or even at post mortem. It is estimated that probably one half the ulcers called gastric are really duodenal. Many are confused with gastric neuroses, especially hyperacidity.

Even autopsy statistics of duodenal ulcer are changing from the meager 2 to 3% of all peptic ulcers to much larger figures. In 50 cases of peptic ulcers autopsied at the Boston City Hospital, 16, or 34%, are classed as duodenal. Codman has shown that the duodenal ulcer may heal entirely without gross scar, which may explain why post-mortem statistics are behind operative statistics in frequency.

Modern surgery shows a steady increase in the proportion of duodenal ulcers at operation. In 1904 the peptic ulcers operated by the Mayos were 73% gastric and 27% duodenal; in 1907, 31% gastric and 61% duodenal, 8% both gastric and duodenal. Instead of the old ratio of 12 gastric to 1 duodenal ulcer, we have the modern operative ratio of 2 duodenal to 1 gastric ulcer. This ratio seems established for the type of chronic severe peptic ulcers which go to the surgeon, but does not *necessarily* hold good for the total number of both mild and severe peptic ulcers.

More than three fourths of duodenal ulcers are in men; this seems to be equally true of *chronic* gastric ulcer.

*Etiology.* — We get nothing new here from the surgical reports except Codman's suggestion that chronic narrowing of the duodenum by pressure of the root of the mesentery may delay the digestive fluids too long in the duodenum and thus favor ulcer.

Past reports of peptic ulcers have seemed to show that high acidity of the gastric juice is common or usual. More recently we have concluded that in *gastric* ulcers high acidity is inconstant, but present in about one half the cases. In Moynihan's long series of *duodenal* ulcers, verified by operation, high acidity was present in only a small minority of the cases.

*Pathology.* — Most duodenal ulcers are close to the pylorus in the folds of membrane like a fissure in ano, usually on the anterior wall, or may encircle the gut. In some there is little thickening, but Moynihan says that chronic ulcers which have caused symptoms are always demonstrable. They may become chronic because they are close to the pylorus, whose constant opening and closing prevent healing. We often find a single round ulcer 1 or 2 cm. in diameter, or two or three in a circle, or a narrow, girdling ulcer. In 10 to 20% of the cases they are multiple. In the majority there are no adhesions. In 47 out of Moynihan's 186 cases, namely, 25%,

* Read before the New Bedford Medical Society, May, 1910.

gastric ulcer was also present. Perforation is due to the accident of location on a free peritoneal surface, just as hemorrhage is due to the accident of location near a blood vessel. The perforated cases usually spread especially to the right, as the fluid flows down outside the ascending colon. "Acute attacks" which recur are probably due to the breaking down of the ulcer after healing, or to attacks of inflammation about the edge of the ulcer, less commonly to the formation of new ulcers. The symptoms may intermit while the ulcer remains open and unhealed.

*Course and complications.* — Codman has shown that the ulcer may heal without visible scar and the mucous membrane grow over it in such a way that it would be overlooked in gross examination. This lessens the value of autopsy statistics in regard to frequency. It may be that fewer duodenal than gastric ulcers are found at autopsy because the former heal more readily. On the other hand, most ulcers described at operation involve the peritoneum and one would expect to find traces at autopsy even if healing occurred. The time of healing is unknown; it may apparently be very slow in small ulcers.

The per cent of cases which perforate is probably small; they are usually chronic ulcers. The reports of different men show great variation: Deaver, 25%; Robson, 10%; Moynihan, 3½%. It would be very misleading to consider this the per cent of all duodenal ulcers which perforate, because perforating cases practically always see a surgeon, and the great majority of other cases probably do not.

A considerable proportion of duodenal ulcers, variously estimated, bleed. Probably a rather small per cent bleed severely, but some surgeons believe that they bleed severely if at all. My own feeling is that most, or all, bleed some and that cases with persistent negative, guaiac or benzidin tests for blood in the stools are probably the exception. We have few reliable data on this point at present. This is a work for the future. The difficulty of getting exact statistics about the bleeding in the milder cases is great. We cannot verify our diagnosis. A suspected ulcer case with no occult bleeding may be an early ulcer or a severe simple hyperacidity. We will discuss the blood tests more fully under diagnosis.

A duodenal ulcer may spread upward and involve the pylorus and cause stricture and may be called a gastric ulcer because ulceration on the stomach side is larger. Cases of duodenal ulcer causing marked obstruction of the pylorus form a separate class with somewhat different symptoms, methods of diagnosis and indications for treatment; they will not be considered here.

While cancer frequently develops on the base of a gastric ulcer, and according to Wilson and McCarthy's statistics about 70% of gastric cancer has this origin, cancer of the duodenum is very rare. Some experienced surgeons have never seen one, and men like the Mayos have only seen a few. I know no satisfactory reason why cancer develops so rarely on duodenal ulcer.

*Prognosis.* — Various opinions have been held regarding the prognosis of duodenal ulcer in comparison with gastric ulcer. Nothnagel always considered the outlook very serious in duodenal ulcer, while Boas considered it better. Recent experience favors the latter view because sometimes good healing occurs, there may be little or no scar, and less tendency to obstruct the pylorus or to degenerate into cancer. Other serious complications, such as hemorrhage and perforation, are about equally frequent. Of Mayo's 27 acute perforations of peptic ulcer, 16 were duodenal, or but little over one half.

*Symptoms.* — Moynihan tells us the symptoms are regular, definite, not easily mistaken and have few exceptions. In looking over case records we are struck at once by their long duration. The majority have lasted three, five, ten or fifteen years. The symptoms are intermittent, often completely so, the attacks lasting a few weeks or months. The large majority of the patients are males in middle life. The most striking and constant symptom is regular recurrent epigastric pain eased by food and alkalies and later returning two to four hours after a meal, the so-called "hunger pain"; after a light meal it appears earlier. In my experience with proved cases the "hunger pain" was less regular and definite in its appearance and many atypical cases were found.

There may be no symptom except the pain if the ulcer does not bleed much or has not attacked the pylorus. Many cases regurgitate acid food or acid contents from the empty stomach. Many have the habit of using sodium bicarboante regularly between meals. Vomiting is very infrequent unless the pylorus is narrowed. The appetite is usually good.

It is evident that many cases closely resemble gastric hyperacidity, and this diagnosis has been severely attacked by the surgeons, who claim that the majority of so-called neuroses with this group of symptoms in otherwise healthy young or middle-aged men are really organic. Moynihan repeats again and again that recurrent severe "hyperacidity" *is* duodenal ulcer. He considers the term dangerous because it conceals a serious organic lesion under a pleasant name.

The surgeons have done us a valuable service in pointing out the frequency of duodenal ulcer and its resemblance to severe cases of hyperacidity, but we must avoid taking an extreme view. Hyperacidity is the largest class of cases in our stomach clinics, comprising one half or more of all the stomach cases in men. The vast majority yield to medical treatment and do not become chronic. It is too much to say that most of these cases are really duodenal ulcer and need operation. Either duodenal ulcer is usually cured by medical means or these cases are mostly neuroses, not ulcer. I am inclined to the latter view. The surgeons must remember that they see a small selected group of stomach cases which have resisted medical treatment and become chronic, and not the rank and file of stomach cases with the symptom hyperacidity.

Moynihan considers the term "hyperacidity"

a misnomer because in his long series of cases the symptom was strikingly present, while an excess of free HCl in the stomach contents was the exception. Medical men have recognized for years that the symptom hyperacidity is the product of two factors, free HCl and a sensitive membrane. If the latter is very sensitive, it takes very little free acid, even less than a normal amount, to provoke the symptom. We naturally expect an ulcerated membrane to be more sensitive than a healthy one. Difficulties disappear if we consider the symptom to mean *too much acid for comfort*, whether the amount is large or small, instead of limiting the term to cases where the chemical analysis is above an arbitrary figure.

It is possible, however, that the "hunger pain" in some of these cases may not be due to acid, but to something else. Two recent patients have especially called my attention to the fact that typical "hunger pain" relieved by food may be the result of other things than acid. These two cases were referred to me with the expectation that they were duodenal ulcers. In both the chief complaint for months was of "hunger pain" coming several hours after meals and relieved promptly by food. Tests showed that neither case had any gastric secretion, either free or combined HCl. One was a neurosis, complete achylia gastrica; the other showed at operation a cancer of the stomach, not involving the pylorus. In neither case was the pain due to acid irritation.

Boldireff has shown that the fasting stomach long after a meal may slowly contract and relax, but it is not easy to see why this should be more painful than earlier, more active peristalsis in the presence of food, nor to explain the prompt relief of pain by mild alkalies by any direct effect or peristalsis. Moynihan has demonstrated by the x-ray that the pain occurs in duodenal ulcer when one half the contents of the stomach has passed out, so it cannot be due to the full or empty state of the stomach or the time of opening of the pylorus. I believe the cause of late pain after meals in duodenal ulcer is the irritation of the walls by acid stomach contents, just as in pure hyperacidity, only more marked because the wall is ulcerated. Even in cases with little free acid the symptom may be marked because of great sensitiveness of the wall. The acid chyme in the duodenum also causes active contraction of the pylorus and squeezing of the ulcer just below.

The pain comes at a time when the wave of gastric secretion is highest and the stomach contents most acid, earlier after a light than after a heavy meal. It is often associated with the vomiting of acid contents. It is lessened by a diet which causes less secretion of HCl and it is relieved promptly by means which dilute, combine or neutralize free acid. Hypersecretion is frequent in chronic ulcer and may give free acid and consequent pain after food has left the stomach.

Gross hemorrhage in severe cases which go to the surgeon is moderately frequent, according to Moynihan, having occurred in about one third of his cases, and is not frequent in Mayo's experience, who regards it not as a symptom, but as a late complication. About the occurrence of occult bleeding, there is a variety of opinions. Mayo considers that it is probably not frequent, that the ulcers are clean and free from granulations. Moynihan says that it is probably very frequent. My own experience agrees with this. I have not yet seen a peptic ulcer demonstrated at operation in any case where careful, thorough examinations of stomach contents and feces gave only negative results. We need more data, more frequent and thorough examinations for blood in this class of cases before we can decide this point.

There are many latent cases entirely without symptoms. All of us who have seen many stomach cases can count a gradually increasing number in their personal experience.

In recent surgical reports, the history has been the main reliance in diagnosis, and the physical examination relatively unimportant. There is likely to be some tenderness in the epigastrium. The analysis of stomach contents is often not characteristic. There is usually a normal or slightly lessened amount of free HCl and we find a considerable number with an excess of free HCl, but the latter is by no means the rule; in fact, Moynihan calls it the exception. Thus we see that the "hunger pain" results more from an over-sensitive ulcerated membrane than from a great excess of free HCl.

*Diagnosis.* — The early diagnosis of duodenal ulcer from simple *hyperacidity* seems to be a matter largely of severity of symptoms and recurrences, and of the presence of occult or gross bleeding. We need more data and a closer observation of cases. The future will decide how many so-called hyperacidities are really duodenal ulcer.

A study of reported cases of duodenal ulcer which have been operated show that they are far removed from the average cases of hyperacidity which throng our medical clinics. They are a selected, severe, recurrent class, usually with serious late complications. I still feel that the medical cases of hyperacidity outnumber the surgical 50 to 1. Moynihan has done us a great service by giving a detailed report of his 189 operated cases of duodenal ulcer. A careful study shows that of the earlier cases not over one fifth were at all likely to be confused with simple severe hyperacidity at the time of consulting the surgeon, and of the latter cases, not over one third. In the others, such symptoms as gross bleeding, severe pain of long duration, sometimes confining the patient to bed, marked loss of weight, perforation, signs and symptoms of pyloric obstruction, and rarely palpable tumor or jaundice, put the cases in another class at once. On the other hand, the earlier stage of many of these cases must have been quite confusing, and *earlier* diagnosis and *earlier* surgical treatment much to be desired, just as it is in gallstones before late serious complications have a chance to occur. *This is the most important point in the recent surgical work, — the necessity for better and*

*earlier diagnosis in the border-land cases in order that the patients may get better and earlier treatment.* For years I have examined all severe hyperacidity cases for an underlying organic cause, such as ulcer, pyloric obstruction or gallstones, and occasionally found one. This search must be even more carefully made in the future and the patient given the benefit of exploration if doubt arises.

I have been much interested in tests for occult blood and have used them for years as an aid in distinguishing gastric neuroses from ulcers and have been well pleased with the results, and thus far none of my cases of so-called hyperacidity which gave a persistent negative test for blood in the stools and stomach contents have to my knowledge proved later to be chronic duodenal ulcer. On the other hand, I have repeatedly examined a large number of peptic ulcers and have not yet seen a single case where a chronic, gastric or duodenal ulcer was found at operation where both stools and gastric contents gave only negative tests for blood. I realize that this differs from the experience with chronic ulcers at the Mayos' clinic in a much larger number of cases.

Bonniger has suggested a test of the sensitiveness of the mucous membrane of the stomach. He introduces 100 or 200 ccm. of decinormal HCl solution. If ulcer is present, this causes sharp pain which is easily relieved by giving milk. If there is no pain, ulcer is ruled out. This is interesting, but not confirmed as yet.

Great difference of opinion exists about the *diagnosis of duodenal from gastric ulcer*, particularly between the physicians and surgeons. Rigel says it is impossible in the majority of cases. Ewald says it is impossible in at least 90%. Dr. Graham, of Rochester, after examining hundreds of chronic ulcer cases and seeing them operated upon by the Mayos, says that if you follow the patients from the examining room to the operating room, you are forced to the conclusion that to locate a peptic ulcer is not only very difficult, but often impossible. Dr. Munro says it is a waste of time trying to locate an ulcer within a fraction of an inch.

On the other hand, W. J. Mayo says that the differential diagnosis from gastric ulcer can usually be made, and relies largely on the "hunger pain" and the location of pain and tenderness from the mid-line to the right.

Moynihan says that the diagnosis from gastric ulcer presents no great difficulty and lays much stress on the *time* of the pain. If it occurs early within an hour, the ulcer is in the cardiac half of the stomach; if from one to two hours after a meal, in the pyloric antrum; if the pain is two hours or more after a meal, in the duodenum.

I have private records of 69 cases of chronic peptic ulcer without including cases in which the symptoms were mainly due to pyloric obstruction. Ten cases, or 15%, are classed as duodenal. In looking over the records of the cases which have come to operation or autopsy and the diagnosis absolutely verified, and considering only cases in which the position of the ulcer was definitely stated, and found far enough from the pylorus to avoid as far as possible any confusion of origin, I find little to distinguish the two classes of peptic ulcers. In taking the histories, I paid especial attention to the regularity and time of the appearance of the pain, its relation to food, the effect of food to cause or relieve it, as an aid in diagnosis from possible gallstones. My records show that pain appeared one to three hours after meals, one-half to three hours after meals, two to three hours after meals, "late" after meals, just as often in gastric as in duodenal cases. It so happened that in a large portion of the duodenal cases the pain appeared very irregularly and had little relation to the usual meals, but was relieved by taking food. Moynihan's contrary experience redoubles my interest in these cases and stimulates even greater care in taking the histories. In some cases the gastric contents were highly acid, but the majority showed normal acidity only, at the time of examination. It may be that in these cases, as in Moynihan's earlier cases, the clearer picture of simple duodenal ulcer is blurred by some complication. Great credit must be given to Moynihan, and great stress laid on his conclusions, for no one has made such a searching study of large numbers of *early* cases of duodenal ulcer verified by operation.

Among the diagnostic points recently emphasized between ulcer above and below the pylorus, some have a little value and others hardly any, and we sometimes get a glimpse of poor physiology.

*Hemorrhage, whether gastric or intestinal.* — Hemorrhage is chiefly found in the vomitus in gastric ulcer and chiefly in the feces in duodenal ulcer, but is very frequently found in both in either class of cases, and has little value in diagnosis in the individual case unless we have persistent blood in the feces, without blood in the gastric contents. If blood is poured into the stomach in gastric ulcer, some is practically always found in the feces. Blood which is poured out in the duodenum is very readily regurgitated into the stomach just as bile is. In Moynihan's series the number of cases having both hematemesis and melena was greater than of those having melena alone.

*The time of pain.* — In ulcer of the stomach it has been said that pain should occur early after meals from mechanical irritation of the food, and in duodenal ulcer the pain should be late after meals because the food reaches it later. This is largely theoretical. I believe that the pain will occur at much the *same time* in these cases and for the same reason. There are two types of pain in any chronic peptic ulcer wherever located: a milder, early kind associated with mechanical irritation of food, and a later kind, much more frequent and important, due to the irritation of acid secretion and secondary spasm of the pylorus. In simple hyperacidity we know that distress, or pain, comes late after food at the time when most free acid is present in the stomach, and if this is true when the mucous membrane is unbroken, how much more will it be true in gastric or duodenal ulcer at the same

time and for the same reason. In short, irritation of the acid contents, and not simply of food particles, appears to be the chief cause of pain in any peptic ulcer.

It is not true that food reaches a duodenal ulcer an hour or two later than a gastric ulcer, or that the pain of duodenal ulcer comes hours after a large meal and earlier after a small meal because of *great* differences in the time of opening of the pylorus. All peptic ulcers are bathed with food in a short time after any ordinary meal. The x-ray shows us that after an ordinary mixed meal, whether light or heavy, with ordinary gastric secretion, traces of acid soon appear, the pylorus opens and food begins to leave the stomach in from ten to fifteen minutes. Moynihan has shown by means of the x-ray that more than half the food has left the stomach in cases of duodenal ulcer before the typical pain appears. The later pain of the large meal is apparently due to the later development of enough free acid to irritate the ulcerated surface. In short, the pain is essentially the same in both kinds of ulcer, appearing one to three hours after meals and relieved by both food and alkalies, but is likely to be *more regular* in duodenal than in gastric ulcer because of the more uniform position of the former. The duodenal ulcer is always in one place; the gastric may be anywhere in an area five or six inches in diameter.

The *position of pain* more to the right is not a satisfactory diagnostic point in duodenal ulcer. The pain is median in gastric ulcer and usually so in duodenal ulcer also.

The *relief of pain* by food is very similar in both gastric and duodenal ulcer and depends more on the size and chronicity of the ulcer, on the amount of gastric acidity and the sensitiveness of the mucosa, than on the position of the ulcer.

The *stomach tests* may be normal in duodenal ulcer and blood may be absent. In gastric ulcer we expect it to be present. It is said that in a very chronic indurated gastric ulcer there may be no blood in the stomach contents even on repeated examination with the present delicate guaiac or benzidin tests. I have not seen such a case, though they undoubtedly occur. High acidity of gastric contents is less common in duodenal than gastric ulcer. On the whole, tests of gastric contents are not of much value in distinguishing an ulcer above and below the pylorus.

The *position of tenderness* is a very deceptive symptom. It is epigastric and rarely sharply defined and is practically the same in both kinds of cases.

I do not believe there is any real difference in *chronicity* in the two kinds of ulcers; both may be acute, and both are very frequently chronic.

It is said that patients with duodenal ulcer are apt to be *better nourished* because they take extra meals to relieve their pain. I do not believe this is an important difference from gastric ulcer. Both kinds of cases are apt to limit their diet and lose weight in acute attacks and to gain in the intermissions, and the severe cases of both kinds have often lost much weight.

There is no doubt that *vomiting* is somewhat less common in duodenal ulcer; a long history of "hunger pain" with absent or late vomiting favors duodenal ulcer. The *character of the vomitus* in peptic ulcers depends on so many other factors besides the position of the ulcer that it has little value in differential diagnosis.

There can be no doubt that all kinds of peptic ulcers are relieved by the *use of alkalies* and that this relief is due to neutralizing the free hydrochloric acid of the stomach and that it is not due to the generation of gas in the stomach. Our most effective alkali is calcined magnesia which does not generate gas.

The differential diagnosis of gastric from duodenal ulcers is not a new question. It has been seriously considered by leading clinicians, and we are not asked to decide it in a new way, but in the good old-fashioned way, by the patient's symptoms. A large majority of gastric ulcers are close above the pylorus, and duodenal ulcers are usually within one-half to one inch below it. I do not believe that in the majority of cases we can locate these ulcers within an inch by the patient's symptoms.

*In conclusion, we must remember that duodenal ulcer is more common than previously supposed, and scrutinize with a special care all severe cases called hyperacidity. We must also remember that it is far more important to distinguish early all peptic ulcers from gastric neuroses, especially hyperacidity, than to try to distinguish the gastric from the duodenal ulcers.*

Gallstones are often confused with duodenal ulcer. They present the only difficulty in diagnosis, according to Moynihan. About 15% to 20% cannot be distinguished before operation. There is nothing that is new here, so I shall pass it over briefly. Gallstones are found more frequently in middle-aged or elderly women, and duodenal ulcer more frequently in young or middle-aged men. Pain in gallstones is more violent, irregular and nocturnal, without relation to food and without relief by food; in duodenal ulcer, is less violent more regular, more related to food and relieved by food and alkalies. Gallstone cases are often fat, and ulcer cases usually under weight. Jaundice is common in the first and rare in the second, while gastro-intestinal hemorrhage is practically absent in the first and common in the second. We have most difficulty in the differential diagnosis of cases with large stones in the gall bladder, too large to pass, which produce chronic symptoms with spasm and without jaundice.

The diagnosis of perforated appendix from perforated duodenal ulcer may be very confusing. This is a matter which chiefly interests the surgeons, and whose treatment is entirely surgical, so I shall pass it by.

Occasionally a case of hepatic cirrhosis with hemorrhage may simulate duodenal ulcer as it does gastric ulcer. The diagnosis is usually made easily from the history and physical examination.

*Treatment.* — The diagnosis is not an indication

for operation since there is good evidence that even chronic duodenal ulcers heal completely under medical treatment. Mayo advises that only cases which have not yielded to a reasonable amount of medical treatment should be treated surgically. Then comes the question, What is a reasonable amount of medical treatment. It is very hard to lay down rules. We must consider the individual case, the nutrition, the social status and the freedom from complications. There is no question that loss of weight and persistent or recurrent distress, pain, or pyloric obstruction sufficient to interfere seriously with normal life and work in spite of careful, thorough medical treatment are good reasons for sending the case to the surgeon. Many of these cases have been kept far too long in medical hands. It is interesting to note that Mayo's cases of mixed peptic ulcers were given ineffectual medical treatment for an average of twelve years before operation. This, or even half this time, will seem unreasonably long medical treatment in the future. We must look over our severe "hyperacidity" and chronic ulcer cases more carefully and give the obstinate ones benefit of surgical treatment much earlier and more frequently than in the past.

*Medical treatment.* — I shall not take up the medical treatment of ulcer in detail for it is well known, but simply emphasize a few points. We should treat the milder cases as we do hyperacidity, carrying out our treatment thoroughly and persistently as long as it is necessary or reasonable. We try to quiet the nervous system and to avoid stimulants of gastric secretion. The foods which stimulate gastric secretion are, briefly, coarse food, hot and cold food, meats and their juices, especially roast or salted, rare or lean meats, alcohol, spices and condiments, salt, carbonated drinks and coffee. In general, we use freely the bland, finely divided foods which have little or no effect in stimulating gastric secretion or which depress it, such as milk, cream soups, bread, vegetables in fine purées, cereals, fats such as cream, butter and olive oil, eggs, boiled meat and fish, soft cheese and cocoa. We neutralize the free acid in the stomach by means of bicarbonate of soda in one-half to one teaspoon doses or by a mixture of sodium bicarbonate with equal parts of calcined magnesia in smaller doses. These are best given just before or just after the habitual time for distress or pain. Little lunches between meals, such as an egg, or milk, or bread and butter, or cracker and soft cheese, may be given to combine with the acid and relieve symptoms. Half-dram doses of hydrogen peroxide in a glass of water after meals may be used. Petri has recently shown that this is one of the most active depressants of gastric secretion. I think the practical value of atropine to depress secretion is very limited on account of its disagreeable by-effects.

The more acute or more severe or bleeding cases should be put to bed. I wish to emphasize only one point here, namely, the modern reaction against any scheme of treatment which depends for any length of time on exclusive rectal feeding. We know the limitations of rectal feeding, that not over five hundred calories per day can be absorbed from the rectum; in short, not over one fourth or one fifth of the daily food which is needed. Thus if exclusive rectal feeding is continued, the patients are starved and weakened, thus sacrificing the body as a whole to one organ, the stomach. Many of us believe that the stomach does better if the acid gastric juice is combined by frequent feeding of bland proteids than by leaving the stomach empty and that the better nutrition of the patient will favor the healing of an ulcer. Lenhartz several years ago advised early feeding by mouth in all ulcer cases, even those with a recent hemorrhage. He planned a diet which is briefly as follows: He gives 200 ccm. of milk in small divided doses and two eggs on the first day and adds one egg per day and 100 ccm. of milk until eight eggs and 1,000 ccm. of milk are taken daily. Four or five teaspoons of sugar are added after the third day, and at the end of a week soft solids, such as soups, gruels, custard, toast, rice, scraped beef and ice cream. Senator has advised using fats in the form of cream and butter as frequently as possible, also gelatine as soft jellies. I have used such a diet steadily for several years in all acute ulcer cases and all chronic ulcer cases with acute symptoms and think the results are decidedly better than where the treatment was begun with four or five or more days of exclusive rectal feeding. The frequent feeding is helpful and the restriction to liquid food is not necessary in either gastric or duodenal ulcer.

The schedule need not be rigidly followed, but varied to suit the case. I do not begin mouth feeding for a day or two after a hemorrhage. I often find it impossible or undesirable to give so many eggs a day, and by using milk sugar added to the milk instead of cane sugar, we can begin on the first day with a tablespoon and easily increase to four or five tablespoons a day and thus add much to the food value of the daily ration. In my experience this régime rarely needs to be interrupted on account of pain, nausea or vomiting. Rectal feeding may be carried on in addition for the first week or one-half week. We must watch the diet for months after the acute attack.

*Surgical treatment* — Recent surgical experience points out that cases with severe, persistent or recurrent "hyperacidity" should be explored for ulcer if they do not yield to medical treatment, especially if the patient is not neurotic. It is unreasonable to trust medical treatment indefinitely where we suspect that a chronic indurated ulcer is present; the majority of these cases do not get well under medical care; they are essentially surgical. The Mayos have shown by interval operation that the symptoms may intermit, while the ulcer remains, open and unhealed. We now ask, What can the surgeon offer, what is the best operation, what is the risk and what the hope of benefit to the patient?

Excision seems the ideal operation, theoreti-

cally, but it is not often done. Its mortality is notably higher than gastro-enterostomy. Mayo, in one hundred and fifty-three cases of excision of the *stomach* for cancer, found that 71% had developed on an ulcer base. This fear of cancer developing on a previous ulcer does not apply in the duodenum. The duodenal ulcer very rarely becomes malignant, and excision is not so necessary. Of all the Mayos' excisions for cancer and ulcer between 1905 and 1909, 210 were done on the stomach and 8 on the duodenum. Of Moynihan's 294 operations on duodenal ulcer, only 4 were excisions, and the rest gastro-enterostomy. He advises excision only when it can be done without any risk of narrowing the gut.

Gastro-enterostomy is the usual operation. It was first devised for an obstructed pylorus, and there was some question whether it was reasonable to use it in simple duodenal ulcer without marked stasis of food or gross hemorrhage, with the expectation of relieving pain and of helping the ulcer to heal and thus of avoiding perforation, hemorrhage or extension. It was found that the acidity of the stomach contents was sometimes much reduced by admixture of duodenal contents through the new opening which appeared to favor healing of the ulcer.

There were some theoretical objections: that it was not needed to relieve pain and that it might not permanently help the ulcer because much of the food would perhaps pass through the open pylorus and the new opening would tend to close if the pylorus remained open. Also it was said operation was not as necessary as in gastric ulcer because the food is better liquefied and less irritating when it passes into the duodenum. There were also the operative risks, the possible formations of adhesions or jejunal ulcer.

The question cannot be settled by theoretical considerations, and even though we have no reported results classified strictly according to the position of the peptic ulcer and according to the presence or absence of pyloric obstruction, the results of operation as reported by the Mayos, Moynihan and others are very instructive They justify the operation in spite of any theoretical objections. In fact, gastro-enterostomy seems to be more successful in the treatment of duodenal than of gastric ulcer. Moynihan advises turning in all ulcers that do not obstruct; the gastro-enterostomy opening may not stay open and the ulcer may heal, but break down later when original conditions recur.

Moynihan has reported operations on nearly 200 cases of duodenal ulcer with a 2% immediate mortality, 79% of cures, 9½% better, 1% no better, 2% of late deaths, and the rest not traced. The Mayos' figures in chronic ulcer are almost identical. These striking figures are the product of great personal skill, large experience and perfect organization. We cannot expect them to be duplicated at present by the great mass of average well-trained city surgeons over the country. It is instructive in several ways to contrast them with the reports of 150 cases collected by Dr. Bettmann and myself, consisting almost entirely of peptic ulcers, both gastric and duodenal, in which gastro-enterostomy was done within the last eight years. They cover the same period of time, but differ in several ways. They were operated by excellent surgeons in a dozen of our largest cities in the East and Middle West; they include both types of peptic ulcer, and they represent, on the whole, later cases, for example, about 70% had well-marked pyloric obstruction. The results were as follows: 10% immediate mortality, 58% well, 6% much better, 22% no better, and 4% late deaths. There is something for *both physicians and surgeons* to do to improve these figures, for *both are equally responsible.* The physician must get a clear picture of *early* symptoms in chronic ulcer, study his cases more carefully and make an earlier diagnosis and not wait for the later picture, which means perforation, severe hemorrhage or marked pyloric obstruction. This early diagnosis should make possible earlier and, therefore, much more effective treatment, just as in gallstones.

The physician should always give medical treatment a fair trial, but this is not his whole duty; he should transfer obstinate cases much earlier to the surgeon. Years of ineffective medical treatment are a reproach if the patient has a chronic ulcer. He loses weight and strength and fresh complications arise which help to swell the mortality statistics and the per cent of failures, when he is finally sent to the surgeon.

Some physicians hesitate about transferring suitable cases to the surgeon because the present results of operation are not as good as could be desired. This attitude is dangerous and unprogressive, for physicians and surgeons are equally responsible for these results and they cannot be improved without hearty co-operation.

The choice of a surgeon is important. He should not be chosen because he is a friend or a good fellow, or a good gynecologist or genito-urinary surgeon, but because of large successful experience with *gastric* surgery. The surgeon's duty is to improve his technic and increase his experience.

A survey of recent reports shows that it is not reasonable to expect more than a 5% immediate mortality, 60% of cures and 20% of improvement in general surgical practice at present.

The surgical treatment of peptic ulcers is much the same wherever they are, gastro-enterostomy or excision, with excision of *gastric* ulcer whenever possible on account of the greater danger of cancerous degeneration.

*Summary.* — We must revise our ideas about chronic duodenal ulcer on the basis of recent surgical reports which show that it is much more common than formerly supposed. Many cases have previously been confused with gastric ulcer, hyperacidity, gallstones or appendicitis. Two thirds of the chronic peptic ulcers which come to operation are duodenal. Three fourths of chronic ulcer cases are men.

The history in early cases is more characteristic than the physicial examination. The early

symptoms, according to Moynihan, are more definite than formerly supposed; the most striking is regular, recurrent "hunger pain" in the epigastrium. We need a clear picture of early symptoms to aid us in an early diagnosis. In my cases "hunger pain" was less regular and definite and many atypical cases were found. The pain is essentially the same in both gastric and duodenal ulcer, but more regular in duodenal ulcer because of its more uniform position.

High acidity of gastric juice is present in only a minority of cases and is less common than in gastric ulcer. The symptom "hunger pain" or "hyperacidity" in duodenal ulcer is usually due to the action of a moderate amount of free acid on an over-sensitive membrane.

Simple hyperacidity is the largest class of stomach cases in men; most cases recover under medical treatment. The severe cases closely resemble ordinary duodenal ulcer. We need earlier and better diagnosis of the borderland cases.

My experience indicates that occult bleeding is very common in duodenal ulcer and a valuable aid in diagnosis. Examinations must be repeated. Negative results do not rule out ulcer absolutely. We need more data.

The diagnosis of duodenal from gastric ulcer is usually difficult in my experience, and much less important than early diagnosis from gastric neuroses, especially hyperacidity. We must distinguish sharply the treatment of *acute* from *chronic* ulcer. The first is chiefly medical; the second, chiefly surgical.

Medical treatment should be tried first in all but perforation cases, but many chronic ulcers are kept for too long in medical hands. The symptoms may disappear without the ulcer healing. It is unreasonable to continue medical treatment of a chronic ulcer for years, if the results are poor.

The medical treatment of gastric and duodenal ulcer is the same. The surgical treatment is much the same, — gastro-enterostomy, with excision of gastric ulcers whenever possible.

The physician and surgeon are *equally* responsible for the present results of operation in chronic duodenal ulcer. They can only be improved by hearty co-operation.

The duty of the physician is earlier and better diagnosis and much earlier transfer of obstinate cases to the surgeon. The duty of the surgeon is to improve his technic. Earlier diagnosis before serious complications ensue should mean earlier and, therefore, much better surgical treatment in the selected cases.

## PRESENT TREATMENT OF GASTRIC AND DUODENAL ULCER. A REVIEW OF THE RECENT LITERATURE ON THE SUBJECT.

BY CHANNING FROTHINGHAM, JR., M.D., BOSTON.

In 1906, at the meeting of the American Medical Association, a symposium was held by the combined medical and surgical sections on the treatment of gastric ulcer. Papers were presented by Hewes, Rodman, A. Lambert, W. H. Mayo and Billings which showed the generally accepted views in regard to the best treatment for gastric ulcer at that time.

In considering the treatment of gastric or duodenal ulcers it is essential that the different types should not be confused. In this paper the following classification has been made without attempting to differentiate between gastric and duodenal ulcers:

Acute ulcers, single or multiple, without complications.

Acute ulcers, single or multiple, complicated by considerable hemorrhage.

Acute ulcers, single or multiple, complicated by perforation.

Recurrent or so-called chronic ulcer, without complications.

Recurrent or so-called chronic ulcer, complicated by hemorrhage.

Recurrent or so-called chronic ulcer, complicated by perforation.

Recurrent or so-called chronic ulcer, complicated by stenosis.

All the above-mentioned authors agreed that the treatment of acute uncomplicated ulcer should be non-surgical, provided that proper medical treatment could be carried out. The medical treatment, at that time, consisted of rest, diet and therapeutic agents. There was some difference of opinion as to the best method of carrying out this treatment.

All the writers emphasized the importance of prolonged rest in bed for from two to six weeks, and insisted that for the following four to six months the amount of physical exercise and mental work should be carefully controlled.

Although, in regard to diet there was a difference of opinion, the ideas practically came under two groups. One urged absolute rest for the stomach for from several days to three weeks, followed by gradually increasing diet, chiefly of carbohydrates and milk. Nutrient enemas were given during the fasting period. This is known as the Leube diet. The other group favored feeding the patients by mouth at once. The diet consisted, at the start, of eggs and milk, and was planned to have a high proteid value, on the theory that the proteid combined more effectually with the acid of the gastric juice. This diet was quickly raised by increasing the amount of egg and milk and adding other substances, such as sugar, scraped beef, rice, zwiebach, etc., until the caloric values had reached the theoretical needs for the patient. This method of treatment was known as the Lenhartz diet.

There were a variety of therapeutic agents suggested, and many different ways of administering them. Bismuth subnitrate, silver nitrate and perchloride of iron were most commonly recommended. These were to be taken by mouth or introduced by the stomach tube after gastric lavage. Olive oil in large doses was a form of treatment recommended by Cohnheim.

In acute ulcers, complicated by severe hemor-

rhage, the general opinion favored treatment by medical means. If the hemorrhage persisted, some writers favored the consideration of operation. If operation were decided on, the procedure was to open the stomach or duodenum and ligate the bleeding point. In the medical treatment both the Leube and Lenhartz diets were favored. Other measures to control hemorrhage were, cracked ice by mouth, ice bag to the epigastrium, gastric lavage with hot or cold water, solutions of adrenalin chloride or other astringents.

Although cases of perforation had been reported as recovered without operation, all these authors agreed that operative interference was the proper treatment and that the earlier the operation after the perforation, the more favorable the prognosis. The operation consisted of suturing the perforation and pelvic drainage in the accentuated Fowler position. Gastro-enterostomy should only be performed in the most favorable cases and then only if subsequent stenosis seemed likely.

In chronic ulcers without complications the medical men favored medical treatment, while the surgeons favored operative interference. The medical treatment for these cases would be the same as for acute ulcer, only more prolonged.

In chronic ulcers with hemorrhage, operation was more generally favored, especially if the hemorrhage showed a tendency to recur. The time for the operation was preferably after the acute hemorrhage had ceased, except in the cases of slight continued bleeding, when operation was advised at once. Gastro-enterostomy was the operation used in these cases.

Perforation in chronic ulcer was treated in the same manner as perforation with acute ulcer.

The treatment of chronic ulcer complicated by stenosis was viewed differently by different writers. It was demonstrated that by a continued medical treatment of rest, diet and gastric lavage, the patients' weight could be maintained and their daily work accomplished. It was also emphasized that unless these patients kept up their treatment, symptoms will return. The surgeon claimed that operation offered a relief from symptoms and a permanent cure of the ulcer. The operation consisted in gastro-enterostomy, with or without excision, depending on the possibility of so doing, and the character of the ulcer area, or, in certain cases, Rodman's resection operation at the pylorus; or, if an hourglass stomach, or a callous ulcer, resection of the stomach.

The above is a short outline of the treatment of the different kinds of gastric and duodenal ulcers in 1906. What advances have been made since then in the treatment of this disease? Have any new facts been added in regard to etiology, so that treatment may be established on a more firm footing in this respect?

Mayo, Codman and other surgeons of late years have been emphasizing the fact that duodenal ulcer is much more frequent than formerly supposed and claim that the old figures of the pathologists are probably wrong. Some consider them more frequent than gastric ulcer. Hoover doubts that duodenal ulcers are more frequent than gastric. Einhorn thinks that the surgeons overestimate the number of ulcers situated around the pylorus. Hort asks whether duodenal ulcer is a local or constitutional disease. Mason, in reviewing the question of hyperacidity as a cause for gastric ulcer, says that it has not been proved as the cause, and all that can be said is that these ulcers occur only where the gastric juice flows, which apparently prevents healing. Work, in a review of the experimental researches on the subject, concludes that these ulcers are due to (1) neutralization of the natural protective bodies current in the blood stream and tissues; (2) elaboration of an endogenous or exogenous cytolytic poison, which is especially toxic for gastric mucous membrane; (3) the results of these factors is a necrosis and desquamation of the gastric mucosa, which is accompanied by a lack of mucus and an increase of hydrochloric acid. Andressen considers that these ulcers are due to a circulatory disturbance. Percy believes that they are dependent upon a chronic cholecystitis. Miller considers that the lymph follicles of the gastric mucosa become swollen, that their surface digests off, and hemorrhage results. Stockton favors Weinland's idea that there is a lack of antipepsin in the gastric mucosa. Wolff thinks that the etiology is still uncertain and that there is no proof that there is anything wrong with the gastric juice. He mentions the frequent relation between chlorosis and ulcer. Lüdin emphasizes the point that an increase in hydrochloric acid is not always an accompanying phenomena. Lenhartz says that there is nothing new in the etiology of this disease from a practical standpoint. Weintraud discusses the different theories as to etiology, but reaches no conclusion. Hoover, Wolff and Ellis have shown the possibility of tuberculosis and syphilis causing gastric ulceration, but they do not think them responsible for all gastric ulcer. Sutherland considers that bleeding from the stomach other than from ulcerations is an entity and calls it gastrostaxis.

Although several theories have been advanced in regard to the etiology of gastric ulcer in man, and considerable experimental work in animals (not included in this review), with the object of producing gastric ulcers has been reported, nothing definite has been produced which will be of value in planning treatment. The important practical point brought out is that hyperacidity does not always accompany these ulcers.

During the last few years the discussion on the treatment of acute gastric ulcer without complications has centered almost entirely upon the diet. The plan of Lenhartz in regard to earlier and more substantial diet has been tried out and opinions formed in regard to it. Many authors have regular schedules of diet for all patients, while others, although adhering to some one principle, vary their diets for the individual case.

All writers to-day, as in 1906, urge the necessity of prolonged rest in gastric ulcer. Rest in

bed at the start with careful regulation of exercise for six months to a year.

In regard to diet in acute uncomplicated ulcer, Martin, in Osler's "Modern Medicine," presents the different views without expressing a distinct preference of any one method. Lenhartz, in 1909, reports on the results of his diet as outlined above and is still enthusiastic over them. By his method he thinks that the patient's general strength is improved so that the healing of the ulcer is accelerated, and that the proteid combines with the gastric juice and keeps it from attacking the ulcer. Craig reports good results with the use of Lenhartz diet in acute ulcer. Obrastzow says that in Russia the Lenhartz diet has been tried out but has not maintained a firm footing. Leube, on the other hand, considers that the statistics for his treatment are more satisfactory. He has seen rest for the stomach cure, when food caused vomiting and bleeding. He doubts that a fasting stomach secretes gastric juice, and feels sure that gastric peristalsis after rectal feeding is less than after a Lenhartz meal. Tabora has gone back to the Leube method as he has had unfavorable results from the Lenhartz method. Schule, in experiments in vitro, shows that Leube's carbohydrate diet has as good acid-binding properties as the Lenhartz diet, but is uncertain which calls out the most secretion. He finds that under the Leube diet patients all return to their original weight after a while. Lüdin says that during the Leube treatment the hemaglobin is as good as by the Lenhartz treatment, but adds that this may be due to concentration. Lüdin also reports that at a recent congress at Wiesbaden the question of the superiority of the Leube or Lenhartz treatment was left undecided. He finds the Leube method satisfactory and less acid after a carbohydrate than a meat diet. Others, he says, find no increase in acid after albumin diet. He finds that cases treated by Lenhartz method do become emaciated and die of inanition, which shows that the power of absorption may also be involved in these cases. Pain has been a bothersome symptom in some of his cases on a Lenhartz diet. On the whole, Lüdin's cases have shown a higher percentage of cures and a greater rapidity in healing on the Leube diet than on the Lenhartz. Weintraud sums up both treatments and thinks that they both have value and should be used according to the type of case. Thus, a robust person may afford to starve for a few days, while a patient in poor condition should have all the nourishment possible. He favors usually a few days of absolute stomach rest, followed by the Lenhartz diet.

A point of interest and dispute closely related to the question of diet is, What does the fasting stomach do in regard to secretion and peristalsis? Cannon says, from his observations on animals, that rectal enemata may or may not cause peristalsis in the fasting stomach, but that it is uncertain whether there is any gastric secretion in response to the nutrient enemas. Hoover claims that muscular activity and secretion persist in the fasting stomach, and that, therefore, starvation does not accomplish its purpose. Bolton says that rectal feeding may or may not cause gastric secretion.

Other authors have modifications of these two diets, or special diets of their own. Thus, Einhorn has a diet schedule worked out for each day. It is a modification of the Leube diet. He begins feeding at once and gives in addition to milk, barley, bouillon and strained oatmeal, and gradually works up to eggs, crackers and scraped beef. He believes in frequent feedings every two hours at first. Recently he has added eggs from the start. He disapproves of meat as he considers it a strong stimulant for gastric juice and that it takes a long time to liquefy and passes through the pylorus in a swollen state.

Gilfillan quotes Ewald as stating that only four hundred calories can be absorbed by rectum, and, therefore, urges not too prolonged rectal feeding. He considers that starch granules irritate and stimulate secretion. Jacobi opposes anything by mouth at the start, and also the use of the stomach tube. Wolff considers that the ideal diet should be as little irritating mechanically as possible, should call forth the least possible secretion, should be rich in acid-binding substances and rich in caloric value. Lenhartz's ideal, he says, is to have a high caloric value, high acid-binding property, and to avoid distention of the stomach. Thus, although similar, Lenhartz's and his ideals are not the same. He has tried the Lenhartz diet without any improvements in the results. Greene protests against following any special diet in all cases. He thinks the Leube diet too poor in calories and the Lenhartz diet demands too much gastric digestion.

Schnutgen, in comparing results from the Leube, Lenhartz and Senator diets, finds the end results about the same, but thinks that by the Lenhartz method the patients get about sooner and lose less weight. The Senator diet is a middle course between the other two and consists of a diet of gluten, fat and sugar. Rolleston and Oliver advise nothing by mouth, not even water, until there is no tenderness on deep pressure over the stomach. They admit that parotitis frequently accompanies this form of treatment. Bloch favors the oil treatment of Cohnheim. He advises 100–150 ccm. warm olive oil on an empty stomach at first, and later one wineglass three times a day before meals. Greene believes in the oil treatment, but thinks that olive oil, unsalted butter and cream in increasing doses is a better way to give it.

From the above it is clear that differences of opinion still exist in regard to the best diet for gastric ulcer. The points that are made clear, however, seem to be that prolonged starvation is not necessary, and probably harmful, and that ulcers can be cured with patients taking food by mouth, which is not intensely distasteful. Another point which this review emphasizes is that it is not necessary to put all patients on the same fixed diet at fixed hours, but that variations n diet should be used to meet the individual case.

Therapeutic measures other than rest and diet have been suggested by the different authors. Martin suggests bismuth subgallate instead of the subnitrate. Lenhartz advocates bismuth so long as blood appears in the stools, iron for severe anemia, and silver nitrate if the bleeding is long continued. He urges not to hurry to empty the bowels, as he thinks the body derives some nourishment by digesting its own hemorrhage. Leube strongly favors hot kataplasmen or thermaphors to the stomach region in acute non-hemorrhagic ulcers. Einhorn favors bismuth subnitrate with magnesium to keep the bowels open. He rarely prescribes silver nitrate. He suggests codeine and atropine for severe pain. Hoover likes chalk and talcum better than bismuth as the latter colors the stools and interferes with detecting tarry stools of hemorrhage. He believes that adrenalin lessens the stomach activity. He warns against using morphia unless you know the patient, as it may cause vomiting. For pain he recommends orthoform, 7 gr., three or four times a day. Weintraud advises the use of morphia. Lüdin does not like Blaud's pills, as iron causes hyperacidity. Rosenheim and Ehrmann did not find aluminum silicate satisfactory, although under the name of neutralon it is supposed to be of value in secretory disorders of the stomach. Obrastzow favors atropine, and Greene thinks that atropine and morphia in pyloric spasm together with alkalies work well. Greene thinks bismuth in large doses unnecessary.

Mathien and Montier, Block, v. Tabora and Bowers all speak favorably of the use of atropine or belladonna. Bowers considers that bismuth subcarbonate is better than the subnitrate. Wolff uses bismuth from the start, and also silver nitrate and atropine, 1 mgm. if necessary. Hort believes in a meat diet in conjunction with an antiserum of antitrypsin and antipepsin to be taken by mouth to take care of all excess of pepsin, trypsin and acid. Thomson, W. H., favors resorcin and potassium bichromate. Kato reports that oxygar does not always diminish and frequently even increases the hydrochloric acid in the gastric juice.

From the above it is quite evident that no specific drug has been found to aid in the healing of these ulcers.

Even more than in 1906 the management of acute ulcers complicated by hemorrhage is considered to belong to the physician. Greiffenhagen says that hemorrhages cause death in only 4–5% of cases, and that operations on these cases can show no better results. Also, he points out the fact that ulcers may be multiple, which would render more difficult operative interference. Kaufmann considers that fatal hemorrhage occurs only on an average of 3%. Different authors show figures varying from 1–5%. Hoover says hemorrhages from acute gastric ulcers are rarely fatal. Weintraud says that it is frequently difficult to find the bleeding point. Finsterer, Craig, Olmstead and Musser say acute hemorrhage is not a surgical complication. Wolff, on the other hand, although admitting that it is often difficult to find the bleeding point, quotes Ewald as having seen two cases saved by gastro-enterostomy for hemorrhage.

It seems fair to treat this complication of acute ulcer as a non-surgical disease. What procedure, then, should be employed in this complication, in regard to rest, diet and therapeutic agents? All agree to absolute rest during the hemorrhage and cessation of diet during the active bleeding. Lenhartz starts in with his diet immediately upon cessation of the hemorrhage. Out of 262 cases, only 18 had any more bleeding. In his last 120 cases he had only one death, and this case had a severe anemia and psychosis. He considers that his diet keeps the acid of the gastric juice from attacking the thrombus. Leube, on the other hand, has seen food cause bleeding and favors absolute cessation of diet. v. Tabora favors the Leube method of treatment in hemorrhage. Obrastzow reports that they use this method in Russia for hemorrhage. Wolff does not find any better results with Lenhartz than with Leube treatment in the frequency of recurrent bleeding. Einhorn favors rectal feeding for three to five days after hemorrhage, with gelatine and cracked ice by mouth. After that period he starts on his own modified diet. Weintraud and Lüdin favor the Lenhartz diet after a period of rest for the stomach. Kaufmann believes that food should be stopped both by mouth and rectum, and he thinks that Lenhartz's method starts up bleeding. Jacobi and Bolton advise against food by mouth at once, and favor rectal feeding. Hort believes in small dry diet, chiefly of meat. Mathien and Montier report that the French believe in rather early alimentation after hemorrhage.

The consensus of opinion seems to be in favor of stopping food by mouth at the time of hemorrhage and for a few days following it, and then to begin with either a light or fairly heavy diet dependent upon which you favor in uncomplicated acute ulcer.

On the side of therapeutic agents and other devices Lenhartz advises 1 mgm. silver nitrate pills three times a day if the bleeding tends to keep up. Hoover favors 5% sterile solution of gelatine every two hours, and 1 oz. of adrenalin 1:1000 solution in 2 oz. of water. Einhorn favors both adrenalin and calcium lactate by mouth. He and Leube favor cold applications to the abdomen. Bowers, however, considers that the ice bag increases peristalsis. Weintraud thinks that gelatine is of no value by mouth and rectum and is too painful subcutaneously. He also does not think adrenalin effective. In one case he had a cessation of bleeding follow an intravenous injection of 10% salt solution. Kaufmann and Jacobi suggest ligatures to the four extremities to check the venous return. Kaufmann also mentions venesection to cause a faint. He does not think that the usual styptics are reliable and warns that after the vasoconstriction effect from adrenalin vasodilation follows. The reports from gelatine and serum are not convincing, and gelatine may

cause sepsis or tetanus. Kaufmann favors bismuth and stomach washing with not over 300 ccm. of water at a time. Wolff favors lead and iron salts and morphia for bleeding. He mentions as a possibility the use of 10% salt solution, but has not tried it personally. He suggests drinking hot water or washing stomach with cold water or a dilute iron solution. Van den Velden claims that hirudin favors blood coagulation and suggests also a 5–10% salt solution intravenously. Hort advises sterile normal horse serum subcutaneously. Stockton strongly recommends washing out the stomach with ice water, or adrenalin chloride, followed by gelatine water, and at the same time external cold applications. Greene says that the stomach tube may cause hemorrhage.

It will be seen from the above that there is no one device which can surely control hemorrhage, but that there are several things which may be tried if morphia, rest and ice bag do not control it.

All writers agree that acute ulcer with acute perforation should be operated upon as soon as possible after the perforation. The surgeons all agree on tying off the perforation and nearly all agree on draining. Recently Blake and Brewer, in New York, have been closing the abdomen without drainage, after flushing out with a Blake tube, in some of these cases with good results. Considerable difference of opinion exists, however, on the question of excision of the ulcer or the performance of gastro-enterostomy.

Moynihan says, Do a gastro-enterostomy when the perforation looks as though it would cause stenosis on healing. Greiffenhagen advises excision if there is sufficient surrounding tissue. Deaver favors gastro-enterostomy after closing the perforation as he thinks it hastens convalescence and prevents recurrence. Gibbon and Stewart advise against gastro-enterostomy at the time of the perforation operation. Finsterer says to freshen edges of perforation and suture and advises excision only in most favorable cases. He admits the value of gastro-enterostomy in stenosis cases, but feels that it takes the patient's strength and should be done at a second operation. He advises washing the general peritoneal cavity and using Luschke's suction apparatus. Mühsam says to excise only when it is difficult to close in the perforation well with suture. In regard to the best time to operate, Heinemann warns against waiting too long for the initial shock to wear off.

What is the best form of treatment for recurrent or so-called chronic ulcers without complications? On this point there is the most dispute as to whether surgical or medical treatment should be carried out. It has been repeatedly shown that ulcers treated by medical means are apt to recur in half if not more of the cases. Clairmont has shown that the fatalities from operation in the hands of experienced men like Mayo, Moynihan, Robson, etc., is less than 5% and that this percentage is growing much less when only recent statistics are considered. Mayo points out the fact that it is in these recurrent ulcers that perforations are most likely to occur and thinks that a chronic callus never entirely heals up. Wilson and MacCarty show the tendency of cancer to develop at site of chronic ulcer. Payr advises operation in ulcer with marked induration or adhesions, which does not respond to medical treatment. Steinthal, Zesas and Deaver favor operation in these cases if life is not rendered pleasant and healing complete by medical means. Moynihan advises operation as soon as recurrent ulcer is called chronic, but admits it is difficult to decide when to call an ulcer chronic. Blad, Heile and Spischarny lay stress on the fact that after gastro-enterostomy the acidity of the gastric juice is diminished and, therefore, it is not so advisable if the gastric acidity is low. On the other hand, it relieves a hyperacidity. Hort says that many chronic cases recover with medical treatment, and some surgical cases relapse. Rubritus says that gastro-enterostomy will heal pyloric and duodenal ulcers, and Bidwell claims operation should be done as soon as diagnosis of duodenal ulcer is made. Spriggs, on the other hand, opposes operating as soon as a diagnosis of duodenal ulcer is made, and Craig favors giving medical treatment a good trial. Syms favors an early laparotomy in chronic cases as the disease may be gallstones or malignancy.

Thus it seems justifiable, in view of the above facts, to advise operation in cases which show a repeated tendency to recur, or in cases that are not ever entirely relieved from symptoms. The best type of operation will be considered later.

Perforation complicating a recurrent or chronic ulcer should be treated in the same manner as in acute ulcer.

In recent years the tendency has been to urge operation on chronic ulcers complicated by hemorrhage, whether the bleeding is in large amounts or slight, but persistent. Moynihan advises operation on recurrent or increasing hemorrhage from gastric or duodenal ulcers. Greiffenhagen urges surgical intervention for chronic bleeding, either macroscopic or microscopic. Einhorn advises operation in the interval following large recurrent hemorrhages which threaten life, and for small persistent losses of blood. Finsterer, Bidwell, Rubritus and others all favor operation for small persistent hemorrhage. The type of operation in chronic ulcers complicated by hemorrhage will be considered later.

In chronic ulcer complicated by stenosis the tendency at the present is towards operation. It is important to differentiate between stenosis caused by mechanical blocking from the induration and scar tissue around the ulcer or perigastric adhesions, on the one hand, and that caused by reflex spasm of the pylorus on the other. Hewes has recently pointed out the importance of recognising small amounts of stasis. If one examines the residue of a fasting stomach, under the microscope, even if it is only one or two teaspoonfuls, it is frequently possible to demonstrate food stasis which would escape attention in macroscopic inspection. Some medical men still favor

treating these cases with careful diet, regulated life and frequent use of the stomach tube. On the other hand, Moynihan says, Operate with narrowing of the pylorus. Payr and Steinthal advise operation in scar stenosis or ulcers with adhesions. Greiffenhagen admits that patients with pyloric stenosis can be kept comfortable by medical treatment, but usually go down hill from undernourishment. He advises leaving early light cases to medical men. Einhorn advises operation in pyloric ulcer with peristaltic restlessness and continuous hypersecretion, in advanced stenosis, and in duodenal ulcer with pylorospasm and beginning peristaltic restlessness. Heile says, Operate in stenosis, and Port says that the operation on gastric cases is rapidly becoming an operation for stenosis according to the statistics. Wolff mentions the use of thiosinamin, which is fibrolysin, in cases of scar tissue and adhesions for the purpose of dissolving and causing to disappear the fibrous tissue. He thinks it is without effect. Paterson writes on the occurrence and cause of jejunal ulcers following gastro-enterostomy. Mayo thinks that true jejunal ulcers are exceedingly rare and that gastrojejunal ulcers are more common. The frequency of these ulcers is much less, however, as operative technic improves. Craig emphasizes the importance of following up the after-treatment in surgical cases in order to prevent an excess of hydrochloric acid from recurring. Musser insists that spasm of the pylorus from hypersecretion and hyperacidity is not a surgical disease, but considers that stasis from organic change is. v. Tabora advises atropine for the treatment of pyloric spasm.

The best procedure at the present time seems to be operation if true stasis can be demonstrated, whether in the gross or by the use of the microscope.

The type of operation depends somewhat upon the site of the ulcer. In chronic gastric ulcers away from the pylorus, Moynihan says excision is the best operation. On the other hand, Greiffenhagen advises gastro-enterostomy with resection and excision only if the case is very favorable, or a suspicion of cancer exists. Hochenegg considers that gastro-enterostomy is the best operation for all types and locations of gastric ulcers, while Payr considers that resection is a better operation. Craig, quoting Cannon and Blake's observation that after gastro-enterostomy on animals, food continues through the pylorus, considers that resection is the better operation. Clairmont's figures show that gastro-enterostomy helped in only 47% of ulcers away from the pylorus, in 62% of ulcers at the pylorus and in 73% of ulcers in the duodenum.

In chronic ulcers at the pylorus or in the duodenum Payr advises gastro-enterostomy, gastro-duodenostomy or resection of the pylorus. In severe cases he advises a jejunostomy under local anesthesia for feeding purposes with a subsequent gastro-enterostomy and resection later. He favors resection over excision. Cannon says physiologically the operation of pyloroplasty where possible is more reasonable than gastro-enterostomy. Greiffenhagen and Moynihan favor gastro-enterostomy for this type of ulcer. Deaver favors usually gastro-enterostomy and occasionally pyloroplasty. He advocates excision if the ulcer is indurated. Wolff favors resection of the pylorus instead of gastro-enterostomy where possible. Rubritus and Syms, quoting Rodman, favor resection in addition to gastro-enterostomy. Rodman, in 1908, pleads for pylorectomy if possible, as it is only a little more serious and much more effective. Mayo, at a recent meeting, summed up the question of the kind of operative procedure by his remarks that in gastric ulcers, excise if possible, and usually do a gastro-enterostomy, and in duodenal ulcer, excise if possible, and always do a gastro-enterostomy.

To return to the original classification of ulcers, in brief, the treatment may be outlined as follows:

Acute uncomplicated ulcer — medical means.

Acute ulcer complicated with hemorrhage — medical means.

Acute ulcer complicated with perforation — surgical intervention.

Chronic uncomplicated ulcer — medical means soon to be followed by surgical if former are unsuccessful.

Chronic ulcer complicated with hemorrhage
Chronic ulcer complicated with perforation
Chronic ulcer complicated with real stenosis
} surgical treatment.

## INDICATIONS FROM A MEDICAL STANDPOINT FOR OPERATIVE PROCEDURES IN THE PRESENCE OF CHRONIC GASTRIC SYMPTOMS.

BY MAURICE VEJUX TYRODE, M.D., BOSTON.

Probably no greater field for strife between medical and surgical men exists than in abdominal affections giving rise to gastro-intestinal symptoms. The medical side argues that surgical treatment, except with serious complications, gives too high mortality and accomplishes no more than medicine. This applies particularly to cases of duodenal and gastric ulcers, gallstone disease and appendicitis with rather indefinite focal symptoms, or at least chiefly those cases of so-called "hypersecretion." The surgical men reply that, as a rule, cases are sent to them only when grave complications exist, which enormously increases the mortality and also decreases the opportunity for complete cure.

Undoubtedly both sides have some reason for their position. The medical men, especially those not well trained in gastro-intestinal diagnosis, and unable to make a fairly positive diagnosis in the face of mild persistent symptoms, fear to take the responsibility of recommending operation. This is frequently on the ground that they have had some sad experiences, such as nervous dyspepsias, killed by gastro-enterostomy, or cases of duodenal or gastric ulcer or gallstones in which the surgeon contented himself with only the removal of the appendix and thus left the patient as badly off as ever or needing one or two more operations, or dying of some complication. These sad results are sometimes to be blamed on the surgeon for not being willing to explore other suspected sources of disease, but it is much more often the physician's fault who from insufficient examination is so uncertain about the conditions that he leaves it all to the surgeon, without special recommendation for thorough search. The surgical side is absolutely right in saying that too great hesitancy and delay occurs in the hands of most medical men. Therefore, there should be a correct position and a standard upon which to classify cases.

My personal method is to place cases in one of three groups after sufficient examination, diet tests, etc. The first consists of those which, to my mind, it is absolutely wrong to give medical treatment, and if the patient refuses operation, I refuse to treat them. The second consists of cases where I am reasonably certain that operation should be performed to insure complete cure or more safety to the patient, but in whom the symptoms and disablement are not sufficiently great to refuse them medical treatment. The latter I only carry out under protest, having thoroughly explained that I cannot promise a medical cure and that they are in danger of certain serious complications. The last group comprises cases of a purely medical type in which excellent results are obtained by medicine or where surgery could be of no avail and where I would oppose surgical interference.

The cases which come to my office or to that of any gastro-intestinal specialist, in the large majority, complain of eructation, burning at the pit of the stomach or esophagus, so-called sour stomach, fullness, distress, regurgitation, constipation, sometimes nausea, vomiting and pain, feeling of emptiness and faintness at the stomach. With these symptoms the analysis of the stomach contents with proper test meals sometimes shows an increase, decrease or normal HCl, occasionally the presence of lactic acid and microscopic or macroscopic vegetable residue, the presence or absence of occult blood, but always very little or thin stomach mucus. The stools are often hard, small and frequently show an increase in fat globules, fatty acid crystals and an excess of half-digested muscle fibers and sometimes occult blood. The urine and the blood show no constant changes.

The cases of this group can be pretty sharply divided into the following sub-groups. Firstly are the gastric neuroses, occurring in nervous fatigue and hysteria and showing either abnormality in the sensory, secretory or motor function, but usually more or less in all three, yet with no organic basis. These include cases with distress, fullness, pressure, eructation, regurgitation and vomiting of the neurasthenics; also many of the cases with nervous increase in HCl frequently classified as hyperacidities or hypersecretions. Gastric crises may be introduced here for want of a better place. Secondly, we have the mechanical conditions, often associated with nervous symptoms, such as gastroptosis or adhesions from other organs interfering with the function of the stomach. Thirdly, a great group, the majority, is formed by a condition which I call chronic non-mucous gastritis and which comprises many so-called hyperacidities, hypersecretions, gastrosuccorrhea, chronic parasecretion and many cases generally passing for nervous dyspepsias, gastric symptoms of Bright's, heart and lung diseases, of the female adnexa, the gastro-intestinal symptoms of chronic appendicitis, gall-bladder disease, pancreatitis, adhesions, cases called gastric excoriations by Einhorn, or chronic hemorrhagic gastritis by Pilcher. I may be sharply criticised for placing a large percentage of cases of so-called hyperacidity and hypersecretion in my group of

chronic non-mucous gastritis, yet there has been experimental evidence to demonstrate organic changes. Korczynski and Jaworski have demonstrated that in cases of so-called hyperacidity or hypersecretion, or from pieces of the stomach excised during the removal of an ulcer which had been accompanied by great hyperacidity, that there were marked changes both macroscopic and microscopic in the mucosa. The latter showed a pronounced "état mamelonné"; microscopically, they saw extensive small round-cell infiltration beneath the raised epithelium which extended downward between the interglandular tissue into the submucosa and even penetrated the tubules of the glands. The peptic cells were degenerated and disintegrated, whereas the parietal cells were well-preserved. These are certainly, to my mind, changes indicating an inflammatory condition and may righteously be classified as a gastritis instead of as a neurosis. Yet, in other cases, rarer ones, of gastro-succorrhea or hyperacidity, they were unable to find anatomic changes. These comprise the class which I place under gastric neuroses. Riegel states that in hyperacidity the pathology is not known because simple uncomplicated cases do not come to autopsy, and takes the stand that there probably is no pathological change; yet he himself reports a case which died of pneumonia where superficial excoriations were found.

The fourth group of our classification comprises gastric and duodenal ulcers. Not alone the gastric, but even the duodenal ulcers may be preceded, produce or keep up not only secretory changes, but also low-grade inflammatory reaction in both the stomach and duodenum. In fact, Fenwick ascribed the "hunger pains" in duodenal ulcer to hypersecretion, which to my mind is secondary to a low-grade gastritis. The fifth group comprises cancers originating from previous ulcerations.

The above-mentioned group of symptoms are by far more common than another syndrome, where pain is rarely found, where the appetite is absent, food, especially meat, causing nausea, the latter symptom being very frequent even at other times, accompanied by a feeling of fullness and distress and vomiting in from one to three hours after meals. This vomiting consists of badly tasting material made up of partly digested food not in large amounts, but containing much mucus. There is also nausea, and vomiting on awaking, of small quantities of tenacious mucus. In these cases the test breakfast shows very little digestion of the bread, but the same is intimately mixed with tenacious mucus; retention even microscopic is not very frequently found; hydrochloric acid is either greatly diminished or absent, lactic acid may be present, but there is always large quantities of characteristic mucus. The stools may be soft or hard, frequently loose or spongy, putrefactive and containing considerable undigested residue, especially connective tissue and elastic fibers. This last symptom-complex comprises the cases called by various authors chronic catarrhal gastritis, chronic gastritis, but which I prefer to call chronic mucous gastritis. These cases are rather rarer than the chronic non-mucous gastritis, and, although they may be occasionally secondary to other affections, are very apt to be primary, due to indiscretions of diet, but most frequently to excessive use of alcohol and tobacco. They are the ones which at autopsy show the greatest diffuse changes in the stomach.

*Pathologic physiology.* — There is no doubt, as has been proved repeatedly, that emotional and nervous conditions have a tremendous influence upon the character of the secretion of the stomach as upon its motility and sensorium. For instance, it is well known that sudden shock or bad news during or preceding a meal may arrest the secretory and motor functions of the stomach, resulting in stagnation, feeling of distress and frequently rejection of the meal undigested. In like manner, continued nervous strain and irritability is very prone to produce an increased secretion of HCl or of total gastric juice with a diminution of the mucous contents, as there seems to be a certain opposite relation between the two constituents, HCl and mucus. It is easy to see how a mucosa either of the stomach or duodenum continually irritated by an over-acid secretion without the protection of the normal thin mucous coating may partake of a low-grade irritation, which may give rise to still further increased acidity and later to the formation of superficial excoriations which in turn may become ulcers by self-digestion. On the other hand, certain conditions or reflexes emanating from other organs may check the formation of HCl when the mucous membrane becomes more prone to infection; thus a gastritis results of the type first described by Einhorn, under the name of erosions, and later by Pilcher as chronic hemorrhagic gastritis. This form is less apt to produce ulcers because the gastric juice usually contains little or no hydrochloric acid, and under these conditions self-digestion is not so apt to occur as proved by the experiments of Bolton.

With inflammatory processes of the stomach and duodenum, it has been repeatedly shown lately that involvement of the gall bladder and pancreas is not infrequent, and, in fact, this involvement is presented by an eminent English surgeon as one of the great dangers in the persistence of a non-operated duodenal ulcer. Thus, cholecystitis or pancreatitis may result from ulcerative duodenitis. Through the reception of improperly digested food, the lower parts of the intestine become involved and it is most common to have some form of low-grade enterocolitis present in cases of chronic inflammation of the stomach, as I have shown in a previous publication. This may give rise either to diarrhea or constipation, but more frequently to constipation, which in itself greatly aggravates the condition. The unnatural contents stagnate in the region of the cecum and produce a low-grade cecitis which next spreads to the appendix. I have frequently had cases coming to me for chronic constipation with pain in both right and left

iliac fossa and exquisitely sensitive at McBurney's point and on palpation of the cecum. These would frequently clear up rapidly upon proper treatment for the colon and stomach. In such cases the test is the treatment. If they do not react favorably, the appendix is probably involved beyond reach, and probably, on account of an anatomical twist, short mesentery or constriction at the neck, will never quiet down and there should be operation soon.

As there is a physiologic correlation of functions of the gastro-intestinal tract, so we have also a very close correlation of pathologic conditions forming a vicious circle.

In going over carefully the early histories of ulcers, one is struck by the great mildness of the first symptoms, their exact resemblance to cases of nervous hyperacidity and easy relief by treatment applied to this affection. This and the fact that in a previously always strong robust man it is not likely or pathologically possible that a callous ulcer would spontaneously form out of a clear sky with no previous changes whatever in the stomach, leads one to the natural conclusion that probably first functional secretory changes occur followed by an inflammatory condition with lowering of the resistance of the stomach and duodenal mucosa, with subsequent erosion, then ulcer formation. In other words, we have a pre-ulcerative stage to duodenal and gastric ulcers.

To continue with our chain, it is easy to fancy that in some cases inflammation of the duodenum may lead to cholecystitis with or without stones; likewise the chronic low-grade irritation of the intestines may spread to the appendix, which, on account of its frequent anatomic malformation and malposition, is unsuited for medical treatment or proper natural drainage of its inflammatory products.

The interesting cycle begins here. It has been proved beyond reasonable doubt by American, French and English surgeons that diseases of the appendix or gall bladder reflexly cause gastric irritation or inflammation which is frequently relieved by removing the remote offending causes. The symptoms are those which I classify under chronic non-mucous gastritis and occasionally show an increase in HCl, but perhaps as frequently a decrease with excoriations, the latter condition having been so well studied by McGrath in cases of appendicitis. With these conditions there is often associated a spasm of the pylorus so that emptying of the stomach is delayed. The pain has been ascribed to this spasm, but I am rather inclined to refer it to the hypersensibility of the inflamed mucous membrane to the retained products of digestion or decomposition. If inflammation is produced of the particular type necessary, it is easy to see how ulcers may result.

When we grasp this correlation of pathologic conditions, we can easily understand the reason for the frequent association of several organic conditions at once capable of giving rise to gastric symptoms. The appended table taken from Fenwick is interesting; these are cases which he calls hypersecretion and most of which I would call non-mucous gastritis, which he had had operated during the last two years with advice to the surgeon to make careful inspection of all the abdominal organs, particularly stomach, duodenum, gall bladder, pancreas and appendix.

FENWICK'S TABLE.

| | Cases. |
|---|---|
| Chronic ulcer of stomach, | 13 |
| Chronic ulcer of duodenum, | 46 |
| Gallstones, | 12 |
| Chronic appendicitis, | 22 |
| Gastric and duodenal ulcers, | 3 |
| Gastric ulcer and appendicitis, | 5 |
| Duodenal ulcer and appendicitis, | 4 |
| Cancer of the pylorus, | 4 |
| | 112 |

As may be seen in 112 cases with symptoms of "hypersecretion," over one tenth had a double lesion as a cause or association practically equal to the number of simple gallstones or simple gastric ulcers. The number of cases of double lesion were one half as frequent as cases of simple appendicitis which we consider so common. The most common cause of the symptoms was a duodenal ulcer, the next was a simple chronic appendicitis, the third was a complication of several conditions and only subsequently came simple gastric ulcers, gallstones and carcinoma. It is not surprising that four cases of gastric cancer showed themselves to Fenwick with perfect symptoms of "hypersecretion," since it has been shown by the Mayos and others that most gastric cancers originate from a previous ulcer. In considering the results of this careful gastro-enterologist who had his operations performed by careful surgeons with instructions for thorough search, we are struck by the fact that in operations performed with this syndrome the chances are very great, at least one in ten, of finding two distinct pathological conditions. I have had a case with three, namely, duodenal ulcer, gallstones and calcareous appendicitis.

If these conditions, gall-bladder disease, chronic appendicitis and gastric and duodenal ulcers, all may produce a chronic non-mucous gastritis, called by Fenwick and others "hypersecretion," the symptoms of these various diseases must frequently be alike, and they are. And unfortunately, these same symptoms frequently represent a non-mucous gastritis resulting from constitutional diseases, as of the heart, kidney and lungs, nervous conditions and indiscretions in living. Therefore, the problem of the medical man is to make an etiological diagnosis, and Mayo is absolutely right when he ridicules the present meaningless German classification of gastric affections.

Occasionally gastric symptoms tend to show a certain type, especially as regards the symptom of pain in gastric and duodenal ulcer, chronic appendicitis and gallstone disease, and on next page is appended a table which I published last year. This, however, is not at all constant, but may occasionally serve as a guide to differentiate the sources of the "hypersecretion."

TABLE OF PAIN.

| | Location. | Radiation. | Time. | Sensitive areas. | Influence of food. |
|---|---|---|---|---|---|
| Duodenal ulcer. | Epigastrium a little to the right. | Right side. | Two to three hours after meals. | Sometimes deep epigastric, — but not constant. Right subscapular skin area (superficial). | Relieved especially by fatty food, as milk, cream, oil and also by alkalies. |
| Gastric ulcer. | Epigastrium. | Left side. | Immediately up to two hours after eating. | Almost always marked at seat of ulcer, very much localized. | Usually aggravates if ulcer is at fundus, but may relieve when pyloric. |
| Gallstone disease (gastric symptoms). | Under right ribs and epigastrium. | To right chest and back. | At any time, but often immediately after eating. | By hooking thumb under right lower costal border can elicit, besides pain, spasmodic arrest of respiration on taking a long breath. | Makes worse, and frequently nauseates. |
| Chronic appendicitis. (gastric symptoms). | Epigastrium and frequently right hypochrondrium. | Down into lower abdomen. | At any time. | Over McBurney's point and sometimes diffuse tenderness at epigastrium. | Usually does not improve. |

I always held the same position as that of Mayo, and which Hall, an internist, has just published, that it is not necessary for the medical diagnostician to make an absolute diagnosis of all the anatomical changes before the abdominal section. These must be made or corroborated by a well-trained and careful surgeon at the time of the operation. The medical diagnostician's part is to decide whether at least one or more of these medically irremediable conditions are present, to recommend laparotomy with instructions to search especially for ulcers of the stomach, gallstones and appendicitis, besides the condition of the pancreas and other abdominal organs. The exact diagnosis may, however, not infrequently be made by a gastro-enterologist.

It is not difficult to decide that a case is a secondary gastritis, due to phthisis, cardiac or renal disease suitable only to medical treatment, or that it is some acute condition, as an acute perforation or acute hemorrhagic pancreatitis, demanding immediate surgical interference. It is not difficult to determine that a case with obstruction and retention is almost invariably a duodenal or gastric ulcer, if not a carcinoma; all needing early surgical interference, since no ulcer which goes to obstruction ever gets well without surgery. Thus it is my practice to use the stomach tube only for diagnostic purposes, never for therapeutic aims, in cases of obstruction, as *those needing stomach washing should have gastro-enterostomy* What is more difficult to decide is whether a case is one of an unhealable callous ulcer of the stomach, a grumbling low-grade cholecystitis due to a stone or a twisted chronically inflamed appendix producing reflexly the symptoms of chronic non-mucous gastritis without focalization; or whether these symptoms are purely the result of altered secretions incident to prolonged nervous fatigue and strain combined with improper dietary.

Certain changes in the composition of the stomach contents, feces and urine have a significance which, taken along with history and physical examination, may aid us immensely. The presence, increase or decrease in HCl to me means but little in differentiating on the one hand between cases due to appendicitis, gall-bladder disease or ulcers, and on the other hand simple non-mucous gastritis uncomplicated by surgical conditions.

Hereafter, I shall use the term "complicated" as meaning complicated with some surgical conditions. The presence of macroscopic retention is decisive in favor of "complicated" disease, and usually ulcer, duodenal or pyloric. Microscopic stasis is oftener found in complicated cases and more especially with ulcers not only in the pyloric region, but even at the cardiac, as I have observed several such cases. This was probably to be explained by reflex spasm of the pylorus. Obvious or occult blood in the stomach contents is considerably in favor of complicated disease, although I have seen it with gastritis of Bright's disease, which in one case cleared up completely under treatment and three years after has had no return of gastric symptoms. Blood does not always mean ulcer, as it may signify erosions secondary to appendix or gall-bladder disease. In the feces in a case of non-mucous gastritis, decreased digestion of foodstuffs is suggestive of complicated disease. Blood in the feces has, to my mind, much more significance than in the stomach contents after we have excluded hemorrhoids, ulcers and excoriations of the rectum and sigmoid by sigmoidoscopic examination. It is fairly characteristic of a complicated condition, and usually ulcer of the duodenum or stomach.

The test upon which I place most reliance in determining between surgical and medical cases is the therapeutic test. The details of my test is to form the subject of another publication. In a general way, if there is not immediate absolute indication for radical treatment, I place all patients with symptoms of chronic non-mucous gastritis on a test diet, which is chiefly lacto-farinaceous, perfectly smooth and usually with lunches between meals. (This differs considerably from the Leube, Lenhartz and other well-known diets.) The patient follows a hygienic treatment of baths, certain forms of exercise and takes bromides to relax the nervous strain and to bring about restful sleep. The bowels receive also appropriate treatment.

Cases of nervous hyperacidity or hypersecretion and of simple chronic uncomplicated gastritis, with or without erosions, improve immensely within one to two weeks, and the improvement remains permanent. Occasionally strain and worry or gross indiscretion of diet bring about another attack, and if these are often repeated, naturally ulcer may follow. Yet, it is my firm belief that if moderate hygienic and dietetic rules were followed by patients in this pre-ulcerative stage, ulcers would more rarely result.

On cases of gallstone disease, or of chronic appendicitis, the effect of the treatment is not very great. There may be a slight improvement in the sour stomach and distress, but some pain usually persists even after weeks, months and years, if allowed to continue.

With cases of gastric and duodenal ulcer, if not too far advanced and inflamed, the results seem wonderfully successful at first, as most of the pain and distress disappears in a short time, and in the past I have had such cases which I believed to be simple hyperacidity on account of the ease with which they were cured each time and because of the rarity of the attacks; yet, on looking over my records very carefully, I found that cases which only came to me once in six months to two years for the relief of an attack did, on cross-examination, admit that between times, although they were generally well, still occasionally had little distress and pain which were promptly relieved by soda. In other words, although cases of ulcer may give the physician credit for having cured them, because they are relatively so much better than before treatment, and because they have learned to suffer a slight amount of stomach distress as a normal condition, yet few if any will admit on sharp cross-examination absolute freedom from any distress between attacks even on a very smooth diet. And this is the diagnostic point between ulcer cases and uncomplicated non-mucous gastritis. This statement is based upon the observation of cases which ultimately came to operation where the diagnosis was absolutely proved.

Advanced stages of ulcer are resilient to the test treatment and show no improvement.

Patients who improve markedly within two weeks under the test treatment I continue to treat, while watching carefully for focal symptoms, and later I broaden their diet. If in a month or six weeks they are entirely well, with no sensitive areas and no symptoms whatever, I regard them as simple chronic non-mucous gastritis with a possibility of ulcer to be revealed later, but as distinctly medical cases. If an attack recurs within a year or more, with the history of not absolute comfort in between times, I suggest operation with the probability of finding a surgical condition at the basis. In cases not benefited at all by treatment within two weeks and having the symptom of pain, I unconditionally order operation. These include inveterate ulcers and many reflex gastrites from appendix or gall bladder.

Concerning the cases of suspected appendix or gall bladder with reflex chronic gastritis which improves somewhat under medical treatment, I continue treatment for a few weeks unless some focal symptoms develop to clear the diagnosis. If in six weeks to two months the patient is much improved, but not entirely, and with some local symptoms, I order operation believing that the gastritis is not simple.

### SUMMARY.

1. Cases in which I order immediate operation and refuse medical treatment after the test diet are those suffering considerable pain and having shown no marked improvement within two weeks.

2. Cases for which I recommend operation and treat only conditionally, explaining risks, are those improved but not wholly cured by test treatment of few weeks' duration, showing some pain and local sensitiveness at either upper quadrant or at McBurney's point.

3. Cases where, to my mind, question of operation does not enter are those when first attack is rapidly and completely cured in two weeks' test treatment; or in others where constitutional diseases form a contra-indication to surgical procedures.

Below are cited, out of various series, some of the most typical cases, illustrating the difference of types and the classification.

Case 1. Mr. T. C., age twenty-one. Father died of stomach trouble at forty-five. Patient had typhoid fever eight years ago. Two years ago distress and vomiting one-half hour after eating, lasted two months. Perfectly well until two months ago, when same trouble started. No pain whatever, but distress from 3 to 7 P.M. and vomits large quantities. Appetite excellent. Examination: Fairly well-nourished, good color, weight 143. No sensitive spot; stomach, lower border, two inches below the umbilicus. Stomach expression gave two quarts vegetables eaten fourteen hours before, strongly acid, with HCl. Clinical diagnosis: Duodenal or pyloric ulcer with cicatrical contraction causing pyloric obstruction. Therapy: Recommended immediate operation. Operative findings and procedures of surgeon (Dr. Bottomley): Old duodenal ulcer nearly encircling the second portion of the duodenum. Posterior gastro-enterostomy and closing of the pylorus. Excellent recovery, never vomited again. Two years after operation has gained 30 lb. and remained perfectly well.

Case 2. Miss C. M., age forty-five. Family history good. First stomach trouble ten or twelve years ago,

when she had an attack of indigestion, with pain across the stomach. Relieved by vomiting. Troubled usually after eating. Attacks formerly came on at intervals of months, but lately has had one for three months without relief, while before they only lasted a few days. Examination: Poorly nourished woman, large frame, weight 149, against her best weight of three months ago of 160 lb. Lower border of the stomach three inches below umbilicus. Visible peristalsis from left to right. Stomach expression gave 500 ccm. with spinach and other vegetable material from a meal taken fourteen hours before. HCl 0.25%. Clinical diagnosis: Pyloric obstruction due to pyloric or duodenal ulcer. Therapy: Recommended immediate operation. Operative findings and procedures of surgeon (Dr. J. Munro): Old duodenal ulcer, gastro-enterostomy with infolding of ulcer. Complete recovery, no return of the symptoms up to the present, two and one-half years after. Able to eat everything.

Case 3. Miss M. P., age thirty-two. Father died of cancer at thirty-six. Grandmother died of cancer. Four or five years ago attack of indigestion with gas, sour stomach, but no severe pain and lasted only a few weeks. Three months ago sudden attack of pain two hours after dinner, lasted until next day, located in the epigastrium, relieved by belching gas. Two weeks later, second attack, lasted one day. Another in a week and another in a few days. Attacks come between meals. Appetite excellent. Not constipated up to three or four weeks ago. Physical examination: Stomach an inch above the umbilicus. Sigmoid slightly sensitive and thickened. Spasm and very sensitive at McBurney's point. Clinical diagnosis: Chronic appendicitis. Therapy: Made but one examination and ordered immediate laparotomy. Operative findings and procedures of surgeon (Dr. Maurice Richardson): Extensive cancer of the appendix and cecum which was completely removed with glands, including several feet of intestine. In about one year the weight, which was formerly 96 lb., increased to 121.

These three cases are the type which I would place in the first class of our classifications where there was no doubt whatever about the ordering of immediate laparotomy without proceeding to prolonged tests on medical treatment.

Case 4. Mr. I. C., age forty-six. Twelve years ago typhoid, had periodic headaches all his life. Four years ago first stomach symptoms, dull and burning pain in the epigastrium and right side and relieved by food. Constipated. Last six months progressively worse, has attacks nearly every day, has lost 10 lb. Physical examination: Weight 139, poorly nourished, lower border of stomach one inch above umbilicus, very sensitive in the right upper quadrant, very slightly sensitive over McBurney's point and no rigidity. As he did not improve after one week's test treatment, and as the pain was quite considerable, ordered laparotomy immediately. Clinical diagnosis: Chronic duodenal ulcer with possibility of cholecystitis with gallstones. Operative findings and procedures of surgeon: Extensive cholecystitis, thickened gall bladder with adhesions, old duodenal ulcer with extensive adhesions and chronic calcareous appendicitis. Surgeon removed appendix and drained gall bladder, but unfortunately did not perform gastro-enterostomy with occlusion of pylorus. Recovery from operation perfect, very few symptoms for six months, during which time he was eating everything. At the end of that time he came back to me with some of the same old pain, coming on two hours after eating and going through to the back. This was evidently the duodenal ulcer lighting up again. Therapy: Placed him on a smooth diet with bromide, magnesia and bismuth. In a month practically free from pain with only a little distress and gain of 10 lb. Recommended him to continue indefinitely upon smooth diet until ready to be operated second time.

Case 5. Mr. P. D., age thirty-four. Father died of throat trouble at fifty-six. Habits rather bad, drinks a good deal at times, smoked incessantly and had a chancer two years ago. Remembered having cramps in stomach fifteen years ago and has been bothered since then a little bit with indigestion. Bad attack of piles ten years ago. Two years ago bad attack of pain in stomach, vomited blood, remained in bed for four months, living on soup and soft diet. Lately has had some burning and pain three or four hours after meals, but this is easily relieved by soda. Constipated but no vomiting. Best weight 170, now 156 lb. Physical examination: Glands in the axilla, supraclavicular space and groins, abdomen not sensitive, stomach two inches below the umbilicus, splashing sounds. Stomach washing showed 200 ccm. with few pieces of vegetable residue. Therapy: Carlsbad salts in morning and smooth diet with lunches. Great improvement in a week and feels pretty well in a month.

Three months later had bad attack of diarrhea with enormous ulcerated hemorrhoids. Operation performed when both hemorrhoids and diarrhea were cured. Nine months later came back for belching and a little distress across stomach, very quickly relieved by smooth diet, olive oil, magnesium oxide, two hours after meals.

Two years later came back with history that he has felt pretty well during the interim, only recently patient was on alcoholic debauch and stomach symptoms have returned. Pain three or four hours after meals and wakes up about 2 A.M. with burning pain relieved by soda. Patient again easily relieved by smooth diet.

One year later again return of symptoms, even though has been very careful with diet. Stomach examination showed marked stasis with HCl, and blood was present in the stools. Clinical diagnosis: Pyloric ulcer; recommended immediate operation. Operative procedures and findings of surgeon (Dr. Wm. Adams): Old indurated ulcer firmly adherent, posterially situated at pylorus. Gastro-enterostomy and pylorectomy. Year after operation, patient is perfectly well, can eat everything.

This is a case where I should have insisted more strenously for operation several years before, yet at that time results were in Boston so discouraging, and the patient so completely relieved by medical treatment, that it was unduly delayed.

Case 6. Mr. R. F., age forty-eight. Father had same stomach trouble and died at seventy-four. Very irregular habits of life, has used much alcohol at times, smokes considerably. Stomach trouble for twenty-five years, consisting of burning pain and distress, always relieved by whiskey and soda up to three or four years ago, when consulted stomach specialist in another city, who made diagnosis of hyperacidity. Since then severe attacks from time to time, fairly well between times. Now bad attack for two weeks, not relieved by rectal feeding and rest in bed. Best weight 152, present weight 139. Well-built man, good color; stomach, lower border, two inches above umbilicus, no sensitive points. Contents contained ¼% HCl, but no residues. On lacto-farinaceous diet, bromide, alkalies and oil, was relieved in two or three days. In twenty-three days had gained 17 lb. Considered himself cured. My diagnosis then (six years ago) was hyperacidity and advised him to keep on smooth régime for fear of another attack. Four months after, patient consulted me again for oppressed distended

feeling. Put him back on diet and ordered more exercise. Six months after that, made me one more visit, when complained of pain across back, like a belt, and feeling tired, but had been working long hours (mental) without exercise and had drunk and smoked considerably. Again relieved. In two months mild attack of colitis relieved in a week by injections. Thus I saw him for one or two visits about every six months until three years ago, always being easily and rapidly relieved by medical treatment. Three years ago had severe attack of burning and distress and paroxysms of severe clutching pains, somewhat relieved by pressing on the abdomen, once or twice daily. No relief by treatment in a week, when ordered operation with the probable diagnosis of duodenal ulcer. As patient's family objected strenuously to operation, advised consultation of four, including both physicians and surgeons. At this consultation all consultants, even surgeon, were against operation except myself. In another consultation held one week later, two physicians were against operation and surgeon and myself for operation. A few days later family accepted operation. Operative procedures and findings of surgeon (Dr. Bottomley): Large indurated duodenal ulcer. Gastro-enterostomy. No symptoms whatever to the present time, three years after.

Case 7. Mr. G. F. Saw him but once in consultation. Age, forty-four. Father died of stomach trouble at sixty-seven, mother died of stomach trouble at sixty-three. Had typhoid fever at twenty-eight, stomach trouble for fifteen or twenty years. Alternating with some good months and poor months, attacks consist of burning, gas and pain; good appetite, not constipated. Seven years ago trouble became worse, but after treatment was all right for two or three years. Five months ago began again, very much worse, with great deal of pain coming on three or four hours after eating and at 1 A.M. Has been under treatment by local stomach specialist for two months on pure milk diet without relief, when left same and returned to his former doctor, who advised consultation. Physical examination: Best weight now 200. Stomach, lower border, two inches above umbilicus, no succussion, no sensitive areas, except over the sigmoid. Could feel indefinite resistance in region of pylorus. Stomach contents, 100 ccm. few coarse pieces bread, no mucus, no HCl. Blood present by benzidin. No macroscopic vegetable residue, but few vegetable fibers microscopically. Feces contained much occult blood. Diagnosis: Chronic indurated duodenal ulcer. Therapy: Gastro-enterostomy with closure of pylorus or resection. Operative procedures and findings of surgeon (Dr. Maurice Richardson): Chronic duodenal ulcer with large mass and induration about an inch beyond pylorus. Posterior gastro-enterostomy. Good recovery.

Case 8. Mrs. D. B., age forty-eight. Ten years ago, stomach out of order, distressed, fullness and gas, vomiting, with sour stomach, lasted about three weeks. Five years ago similar attack. Three weeks ago similar attack, yet the attending doctor thought she greatly exaggerated the pain, and the neurasthenic element was very strong. She was very constipated. Physical examination: Emaciated, rather pale, abdomen soft and patulous, could distinctly feel descending colon and upper sigmoid, which was thickened. Sensitive resistance under left ribs, could palpate right floating kidney, also appendix, which was quite sensitive; stomach, lower border, one inch above umbilicus. Rectal examination showed impacted large ball feces, size of baseball. Stomach contents: 50 ccm. clear, watery, with partly digested bread, HCl increased, very little mucus, few minute pieces lettuce from meal fourteen hours before. Leucocyte count, 5,000; x-ray, no stone in kidney or gall bladder. No improvement on test treatment for one week. Diagnosis: Indefinite, question of ulcer, cancer of stomach, cancer of splenic flexure of colon and chronic appendicitis. Therapy: Laparotomy with careful exploration. Operative findings and procedures of surgeon: Chronic indurated ulcer of the cardiac end of the stomach adherent and posterior. Gastro-enterostomy. Three months after operation, on the lacto-farinaceous diet, patient is quite comfortable, with no severe attack of pain, only a small amount of distress, gain in weight 5 lb. The surgical treatment of this case might have been greatly improved upon if surgeon had resected the ulcer according to the method of Mayo, because she is in danger of malignant degeneration. He also should have removed the appendix, as she is still quite sensitive in that region.

Case 9. Mrs. E. S., age twenty-seven. Family history and past history negative except an attack of appendicitis at fifteen years of age from which she recovered until four years ago. Sick headache and vomiting since childhood. Four years ago appendectomy and salpingectomy performed and curettage six months ago by surgeon, who refers her to me for stomach trouble. Stomach worse for last seven or eight months, much distress after eating and attacks of vomiting of very sour material three or four hours after eating. During last two weeks has vomited nearly everything. Best weight 180 four years ago; last September, 150; present weight, four months after same, 140. Physical examination: Sensitive over descending colon, moderately sensitive in the region of pylorus, and slightly sensitive over appendix scar. Could feel slight resistance in region of pylorus. Stomach washing, 150 ccm. Bread fairly well digested, no macroscopic vegetable residue, but few microscopic vegetable fibers, no free HCl. Stomach two inches above umbilicus. On first week of test treatment considerable improvement, no more vomiting, but second week pain and vomiting recurred, when I ordered laparotomy. Clinical diagnosis: Ulcer of the pylorus or erosions and pylorospasm, secondary to reflex from appendix adhesions. Operative findings and procedures of surgeon (Dr. Wm. Adams): No visible or palpable ulcer in stomach or duodenum. No inspection made for erosions. Great omentum tied into the appendix scar, causing considerable traction upon the stomach. Surgeon divided omentum. Complete recovery, no return of symptoms after one year. This patient probably had erosions and pylorospasm due to the interference with the motility of stomach, and when this interference was relieved, both these conditions ceased.

Case 10. Mr. E. H., thirty-six years of age. Family history negative, except constipation and nervousness seems to run in the family. Has had children's diseases and periodic headaches since childhood. Four months ago, after taking headache powders, felt pain in his side, which has not left him, and has had much burning, distress and pressure with no relief from treatment. Best weight, six months ago, 150; present weight, 132. Physical examination: Stomach, normal position; slightly sensitive under right ribs, also at McBurney's point. Rather rigid on right side, yet pain was so little, patient thought it was not much more than anywhere else. Diagnosis: Question of gastric ulcer or of erosions with chronic appendix. Sent him back to family doctor (in another city) with my test treatment, with suggestion to examine him again in a month. One month later immensely better, but not entirely well and advised the doctor that, in spite of improvement, thought he would need operation and if willing let me see him again. Came again in five months,

giving history of having been in fairly good condition in meantime, but had now return of trouble. At this time there was distinctly localized sensitive area in the epigastrium, besides slight tenderness at McBurney's point. Diagnosis: Gastric ulcer and chronic appendicitis. Therapy: Advised gastro-enterostomy with possible resection and closing of pylorus and appendectomy. Operative findings and procedures of surgeon: Chronic appendix and gastric ulcer; excised ulcer and removed appendix. One year after, patient again referred to me for return of stomach trouble; placed him on smooth diet, advised his physician that there was probably return of the ulceration and that he might have to be operated again in the future. Now, six months after this, have heard that he is doing very well, but must stick to smooth diet.

This case was badly managed from a surgical standpoint, as not only resection, but gastro-enterostomy, should have been performed, as gastric ulcers are sometimes multiple or at least the tendency exists to the formation of another if gastro-enterostomy is not performed.

Case 11. Mrs. J. G., age thirty-one. Family history negative, has had attacks of indigestion all her life, with occasionally diarrhea and in between times has suffered from burning and distress after meals. Examination shows stomach in normal position, but rather sensitive over the colon, ascending, transverse and descending, which with feces confirmed a low-grade colitis. Stomach washing: Negative, except increased HCl. Constipated between attacks. Soon and greatly relieved by smooth diet and proper treatment of the colon. For four years would return for treatment at intervals of about six months with history of acid stomach, nausea, vomiting and some pain in the lower bowel. Two years ago, appendix was felt sensitive and ordered operation which patient refused. Went away and never felt better in her life for one year. At last examination found her distinctly sensitive at the appendix and refused to treat her any further unless operated. Clinical diagnosis: Chronic appendicitis with secondary chronic non-mucous gastritis. Operative findings and procedures of surgeon (Dr. Wm. Adams): Old chronic appendix bound with adhesions. Appendectomy. Complete relief of all symptoms up to present time, six months after. Can now eat things that never could eat before.

Case 12. Mr. D. M. C., age fifty-five. Mother, stomach trouble all her life, also sister and one brother. Trouble started thirty years ago with heart-burn, feeling of pressure and pain and vomiting right after eating, but only periodic attacks. Ten or fifteen years ago attacks grew more frequent, one every two or three months, usually due to overloading the stomach or being tired. For last six months has had some trouble nearly all the time. Lately has a sharp pain in the lower left chest one or two hours after eating, relieved by food; appetite excellent, but afraid to eat. A little constipated, belches up sour material. Usually relieved by soda and hot water. During the last few weeks worse, symptoms come on at night one or two hours after retiring. Weight, six months ago 145, now 135 lb. Physical examination: Sparely built man, stomach one inch below the umbilicus, local sensitiveness at the epigastrium. Stomach contents: 200 ccm. bread well digested, free HCl 0.25%. Occult blood present and few microscopic vegetable fibers. On test treatment, enormous improvement, but not entirely well. Diagnosis: Gastric ulcer, situated near the pylorus. Therapy: Recommended laparotomy with pylorectomy if ulcer found. Patient's family refused operation, so patient has kept on my diet for one year, feels very much better, no night pain, only a little burning in day, relieved by medicine. Gain of weight, 15 lb.

This is rather an unfortunate decision of the family not to operate, and it is my belief that the ulcer is on the gastric side and very prone to undergo carcinomatous degeneration.

Case 13. Mr. J. K., age twenty-nine. Attack of headaches once monthly for ten to fifteen years. Five years ago, distressing pain in stomach and constipation, for which doctor gave him malt and cascara with relief. For the last few months has had much pain, distress and burning and knawing, relieved by food for two hours. His physician has cut down almost every article of diet without relief. Best weight six months ago, 146; two months ago, 138; now, 132. Stomach, lower border, one inch below umbilicus, very sensitive two inches above and one inch to the right of the umbilicus, slightly sensitive over cecum and sigmoid. Stomach contents, 300 ccm., normal HCl, bread well digested, some black pigment. Benzidin test positive. No vegetable residue. Test treatment for two weeks gave immense improvement. Diagnosis: Chronic gastric or duodenal ulcer probably pyloric. Therapy: Recommended operation as only chance of complete cure. Patient disinclined, therefore followed under his doctor's care the diet and treatment, but in three months had another most severe attack from which he recovered in a month and now feels (six months after) tolerably comfortable on lactaceous diet.

This case in a young man of twenty-nine is one which certainly should be operated on account of the great chances of complications later. The pylorus will close entirely in the space of a few months and years, then he will willingly come to operation if some intercurrent disease or complication does not carry him off before.

Case 14. Mr. P. M., age thirty-seven. Had dysentery and complication of diseases while fighting in Spanish War of 1898. His stomach out of order ever since. Everything burnt him, distressed and caused gas, but no sharp pain. Best weight before war, five years ago, 151; now 133. Physical examination: No sharp sensitiveness anywhere, just uncomfortable, with pressure on the epigastrium. Stomach contents showed increased HCl, otherwise normal. Lower border of stomach nearly to umbilicus. Reacted in two weeks perfectly to test treatment, had no further distress and gained 5 lb. In two months had gained 20 lb. and in two years 26 lb., which he has retained up to this time with complete freedom from stomach trouble five years after. Diagnosis: Chronic non-mucous gastritis with myasthenia, due to debility from fevers in tropics.

Case 15. Mr. J. H., age thirty-two. Family history negative. For last three months has suffered terribly from distress and gas in stomach with frequent vomiting of meals, has lost from 130 down to 95 lb. Has been under care of local stomach specialist, who has fed him chiefly on Mellin's Food. Patient is very nervous and introspective, convinced that he has a serious disease from which he will never be cured. The specialist told him it was chronic gastric catarrh, but he thought it cancer. Physical examination and gastric contents revealed absolutely nothing abnormal. Diagnosis: Neurasthenia with gastric focalization. Therapy: Ordered large meals of meat, vegetables and milk with meals, between meals, assured the patient that he had absoutely nothing organic and made him walk from two to three hours daily. He has never vomited again to this day, ten years after, and has gained steadily in weight, 60 lb., has remained always free from gastric symptoms with the exception of an attack three years ago, while under particular great nervous strain.

Case 16. Mrs. E. L., age sixty-one. Family history good, husband died of cancer of intestines two years before; has had stomach trouble for three years with distress, burning and little pain after meals, often nausea. Two weeks ago pain has been much worse, when she vomited one-half cup of clear red blood. Physical examination: Weight 142, heart somewhat enlarged, second aortic accentuated and rough, pulse irregular, temporal arteries tortuous. Stomach contents acid, but no free HCl, no retention, occult blood present. Urine gave from 20–30 casts per slide, a trace of albumin, quantity around 1,000 ccm. Smooth diet with test treatment caused entire relief of trouble. Diagnosis: Chronic non-mucous gastritis with erosions or ulcer, secondary to arteriosclerosis and chronic nephritis. Patient gained steadily on treatment and had been practically entirely free from any gastric symptoms and has gained greatly in strength up to the present, three years after.

REMARKS ON CASES.

Cases 1, 2, 3, 4, 5, 7, 8, 12, 13, illustrate those of Class 1, where operation should be immediately ordered and where it was obvious that medical treatment could do no permanent good. Case 6 in its earliest stages, Cases 9, 10 and 11 in their earlier stages, Case 11 in its earlier stages, illustrate the type where operation should be thought of and in the present light of our knowledge advised to the patient.

Cases 14, 15, 16 illustrate cases where surgery is not in question.

Case 16 might have been thought operative by some surgeons, yet, in view of the serious arteriosclerotic changes and chronic Bright's, and also of the great immediate relief on the test treatment, and considering the age, it seemed prudent to advise against such measures. This was substantiated by the future history.

### SUDDEN DEATH FOLLOWING A PROPHYLACTIC DOSE OF DIPHTHERIA ANTITOXIN. AUTOPSY REVEALS STATUS LYMPHATICUS.

BY SYLVESTER F. MC KEEN, M.D., ALLSTON, MASS.

The extreme rarity of the above occurrence induces the writer to report the following case:

In the patient's family, a servant, with a history of sore throat for several days, was found to have diphtheria and was removed to the hospital. The other members of the household had been pretty thoroughly exposed to infection, and it was, therefore, deemed advisable to give them all prophylactic doses of antitoxin. Consequently 500 units were administered to a second servant, also to the mother and sister of the patient. The latter, a girl of seventeen, was at high school, and it was arranged that she should call at the writer's office on her way home, which she did. Casual examination showed her to be well-developed and nourished, but of a pasty complexion. As in the case of the others, 500 units of state antitoxin, with the usual aseptic precautions, were injected deep into the deltoid muscle. Following this procedure, the nose and throat were explored to find a possible cause for a sort of chronic coryza. The nasal passages were found to be unobstructed, and the mucous membrane practically normal. There were some adenoids and very slightly enlarged tonsils. After this examination the patient sneezed a number of times, but otherwise felt all right and seemed not at all nervous or disturbed. She left the office with her sister, to whom she complained immediately on reaching the sidewalk of a "stinging all over." They at once turned back to consult the writer. The patient grew rapidly weaker, collapsed on the steps, was at once carried in and laid on the floor. Already she was completely unconscious, cyanotic and pulseless; breathing was difficult, and froth and serous fluid ran from the nose and mouth. There were no convulsive movements. The body was limp; the face looked swollen; the corneal reflex was absent. In spite of artificial respiration, rhythmic traction of the tongue, and hypodermics of strychnia, death rapidly ensued. Less than fifteen minutes had elapsed from the time the antitoxin was injected until the patient was dead.

The autopsy (performed by medical examiner Dr. W. H. Watters) showed a persistent thymus gland, weighing approximately 25 gm., and its left lobe extending to about the level of the third cartilage; numerous enlarged lymph nodes in the mesentery, swollen Peyer's patches, an enlarged spleen and small adenoids. The heart was normal. The lungs were negative and showed very little edema. The kidneys and other organs appeared normal. The anatomical diagnosis was, therefore, *status lymphaticus*.

On inquiring further into the history of the case, the following facts were elicited: The father died of valvular heart disease. The mother is living and robust, but suffers from hay fever and chronic rhinitis (no untoward results followed her dose of antitoxin). The only sister is healthy. The patient had had measles and scarlet fever. For several years (although not lately) she had suffered off and on from attacks of asthma ("thymic asthma"?). For this condition she was treated by a physician, who found at that time a very slight but persistent trace of albumen and a leucocytosis. He advised removal of adenoids and tonsils, but operation was refused (perhaps fortunately!). It was said that laughing often brought on a wheezing attack. For some time past she was troubled by a slight chronic watery rhinitis (vasomotor?). She was always pale, although the Tallquist test a few months ago showed 100% hemoglobin.

## Reports of Societies.

### BOSTON MEDICAL LIBRARY IN CONJUNCTION WITH THE SUFFOLK DISTRICT MEDICAL SOCIETY.

Meeting of Jan. 18, 1911.

Dr. Wm. J. Mayo, of Rochester, Minn., read a paper on

SOME OBSERVATIONS ON THE DISORDERS OF THE STOMACH AND DUODENUM, WITH ESPECIAL REFERENCE TO ULCERS.[1]

DISCUSSION.

Dr. F. C. Shattuck: In the first place, I wish to express the obligation every physician must feel to modern surgery, which, among many lessons, has taught him much with regard to the pathology, symptomatology and treatment of peptic ulcers. Among

[1] See Journal, p. 477.

surgeons, none has contributed more than our guest of the evening, Dr. Mayo.

Not knowing exactly what Dr. Mayo was going to say, and wishing to state my position on this important matter clearly, I have put it in writing. If all surgeons were Mayos, with a Rochester hospital organization, I might modify my views in some respects.

Surgery has developed and is constantly adding to our knowledge of the "Pathology of the Living," as Moynihan well puts it, which varies in important respects from that of the dead. Dr. Holmes compared an autopsy to the inspection of the fireworks the morning after the Fourth of July. The abdominal surgeon studies them in action. The Roman augurs forecasted the future by the inspection of the entrails of slain animals. The modern surgeon not only forecasts, but radically modifies, the future through the inspection of the entrails of living men.

It seems to be a law of progress that some individuals must suffer, must be sacrificed, for the benefit of the race as a whole. This law, if such it be, has been exemplified in gastric surgery. We must not allow our sympathy for the individual to paralyze our efforts for the race. At the same time, we must carefully, critically, prayerfully, consider each step toward progress — aim to achieve the greatest possible good with the least concomitant evil. A more conscientious man than Beau Brummel would not have needed to fill a basket with failures before achieving a perfect necktie. Waste in its simplest form is wrong. Needless waste of human life, needless addition to human suffering, is criminal.

As far as I remember, Joslin and Greenough were the first to show in adequate figures how many cases of peptic ulcer relapse, or even keep their symptoms, after treatment in hospital. Could an equally broad study in private cases have been made, covering the same period, I believe that decidedly better results would have been shown. I also believe that results are better to-day in both classes of cases, for medical treatment has not stood still, and, above all, the importance of prolonged dietary restriction is far better understood. This is, and must continue to be, more difficult to secure in hospital than in private cases.

As I look back over thirty-five years of practice, both hospital and private, case after case comes into my mind of complete and permanent recovery from peptic ulcer, gastric and duodenal alike. Many of these cases to-day coming first into the hands of the surgeon would be operated upon, some of them coming first into the hands of a physician. There has been and is error on both sides. Some physicians are too conservative; some surgeons too radical. Some physicians do not seem to understand and carry out the best medical treatment; some surgeons are less experienced and skillful than others. But physicians and surgeons are, I believe, getting together and finding out when, where and how to operate. As yet the end results of surgery are not comparable in time to those of medicine; operative interference is still too young.

In view of the demonstrated tolerance of the abdomen to all sorts of clean interference, and of the fact that medical treatment left a considerable proportion of cases partially or wholly unrelieved, it was only natural that the surgeon should try his hand, even that some enthusiasts should maintain and act upon the opinion that every case of dyspepsia which does not promptly yield to medical treatment should be operated on. The time limit of medical treatment has been stated as a few weeks. That the ardor of the chase has led to unnecessary and, therefore, unwise operations, I think no one can question. To-day the leaders pick their operative cases with more care and judgment and have acquired great skill. Many followers, however, have neither learned the limitations of operative usefulness nor acquired the operative skill which must be therewith combined to minimize the dangers of plastic operations on the stomach. I have been forced to the conviction that even gastro-enterostomy is a major operation, and that the 2% to 5% mortality of A and B may grow to 10% and 15% in the hands of M or N, and even higher yet in the hands of Y and Z. It seems to me that no surgeon, save in an emergency, should undertake stomach surgery in man before he has acquired considerable skill on animals.

Much of what I have said may be trite, may be even Rooseveltian platitude, but the physician faces, it seems to me, a serious responsibility in advising gastro-enterostomy by the average surgeon.

In the past year I have had personally to do with seven cases of stomach surgery. All seemed to be fair risks. In none was there needless delay before operation. Two died within a week, one within two weeks of operation. All three were gastro-enterostomies for benign diseases. One died of general peritonitis. The second had a previous gastro-enterostomy five years before, with freedom from symptoms for three years following. The symptoms then gradually returned. At the second operation it was found that the opening made five years before had closed and the pylorus was stenosed. Another gastro-enterostomy was done. He died of bronchopneumonia. The third died of empyema, clearly, I think, of subdiaphragmatic origin.

In the past three months I have had in my hospital wards three cases which in my judgment never should have been operated on. One had gastro-enterostomy in Edinburgh in July, 1909. Nothing but slight paleness and induration of the duodenum near the pylorus was found; the existence of ulcer was not considered certain. No abatement of his symptoms followed. Aug. 4, 1910, he was explored at the Massachusetts General Hospital. Fourteen inches of the jejunum was found protruding through the hole in the mesocolon made at operation No. 1. Aug. 20 he was opened again for symptoms suggestive of perforation. None was found. The omentum was somewhat tangled about the colon. Sept. 10 he was transferred to the medical ward, and in the next five weeks lost all symptoms, and gained 14 lb. in weight. Several weeks later he reported himself as doing well. The evidence seems clear enough that proper medical treatment at first would have saved him three operations and a year's discomfort.

In the second case, also of gastro-enterostomy, done in a metropolitan hospital, four subsequent operations for adhesions and one thing and another were performed, and the sixth was done by Dr. F. T. Murphy, who did his best to restore the natural condition.

In the third case Dr. Codman has made the same effort.

A recent case has emphasized the lesson that even when stenosis exists, operation is not always called for. A middle-aged man entered my ward last summer. The records showed that he had been in the hospital under my care in 1898, with moderate dilatation, capacity 2,900 ccm., due, as was thought, to duodenal ulcer and pyloric stenosis. He improved under treatment; was discharged; washed his stomach daily before breakfast; every second day; then less frequently and finally ceased doing so. He was practically well, and worked steadily, until he got to drinking hard, and for some months before entrance in 1910 he had much discomfort and several times vomited small quantities of blood. Under diet and lavage he got

better, though the stomach did not empty itself. He was discharged about a month ago, having gained 29 lb. in eight weeks. He now reports that he has no residue in the morning, no discomfort, and has gained 7 lb. more since his discharge. Until he reports next he is to wash his stomach only every other day.[3]

Among the end results of gastro-enterostomy may be mentioned vicious circle; tormenting adhesions; closure of opening and return of symptoms; the formation of a new ulcer at the seat of entrance of food into the intestine through the new opening. These presuppose recovery from the operation.

Moynihan[3] says: "The arguments in favor of the surgical treatment of all chronic ulcers of the stomach and duodenum are already sufficiently strong. No other treatment than that which the surgeon offers can do more than relieve the patient to some extent of his sufferings when once a chronic ulcer is established in the stomach; for if the ulcer lying near the pylorus heals, its cicatrix, while steadily undergoing contraction, is causing a constant mechanical interference with the movement of the stomach."

With the best will in the world to keep an open mind, I must protest against such a statement as this, which runs so counter to my personal experience, and also as I believe to that of physicians in general.

Since writing the above two more cases showing the possible end results of abdominal surgery have come into my wards. One was a woman whose abdomen was explored in July, 1910, to see whether she had cancer. None was found, but an inactive appendix was removed. She entered my ward about Jan. 1, with vague abdominal symptoms, of which diarrhea and discomfort were the most prominent. The afternoon preceding the reading of Dr. Mayo's paper her condition suddenly became grave; a surgical consultation was held that evening; a probable diagnosis of peritonitis was made, but operation not deemed advisable. She died the next morning, and the autopsy showed a chronic volvulus about an adhesion resulting from her operation of last summer.

The second case is that of a man on whom posterior gastro-enterostomy was done within a year for benign pyloric stenosis and stasis. Temporary relief followed, but recently the symptoms have all returned in full intensity. The capacity of his stomach and stasis are both no less than before the operation.[4]

Dr. H. F. Hewes: The record of work upon duodenal ulcer which Dr. Mayo has given us is of supreme interest to the practitioner of internal medicine, in that the results which he has obtained in the application of surgery as a therapeutic agent for the treatment of this disease give promise of the advent of a means of cure of a condition hitherto more or less untractable as regards permanent cure in the hands of internal medicine.

My experience with duodenal ulcer of the type expressly specified by Dr. Mayo as demanding surgical interference, chronic ulcer causing mechanical obstruction of the duodenum or pylorus, has indicated to me that it is not curable by therapeutic measures in the possession of medicine other than surgical measures.

The condition can be relieved for the time by measures of rest and diet. Patients may appear for periods from one to three or four years to be absolutely cured, but they seldom continue without occasional recurrences at best, and often very temporary periods of relief from symptoms are the best result that can be secured.

Such being the case, any measure which offers a permanent cure of this condition must be hailed with enthusiasm by the medical practitioner. Dr. Mayo's records would suggest that such a measure has been found.

If surgery can perfect itself generally so that so good a percentage of good results can be obtained by its application to this condition as Dr. Mayo's records indicate, the application of this therapeutic method to the treatment of this disease will become, it seems to me, imperative.

There is, of course, at the present time some uncertainty as regards the permanence of the cures obtained under the application of surgery. The period of a general application of this method is a recent one and sufficient time has not elapsed after operation, in many of the cases recorded as cures, to prove absolute cure. I have seen cases where surgical treatment appeared to be successful recur after a period of three years. If the cures are not permanent they are in many cases not better than those accomplished by the measures of internal medicine. But it is my opinion that our knowledge of medicine at the present time indicates the trial of surgery in all aggravated cases of their condition, cases in which definite obstruction of the duodenum or pylorus is demonstrable.

We have all had some bad results in our surgical cases, but I feel that these cases are intractable to other measures and that surgery is the rational means of cure, and that if it is given a chance to perfect itself along this line, it will finally achieve good results generally. I am not sure that the present operation is the best one, but that operative interference of some kind offers our best hope of cure I feel assured.

Having for some time been of this opinion that surgery is indicated in conditions of duodenal ulcer, at least in cases of this condition of the type described, I have been making a special study of the means of diagnosis of this condition. What I have endeavored to arrive at is the establishment of a knowledge of a symptom complex of duodenal ulcer, the determination of which in a case will enable the physician to decide definitely as to diagnosis and whether it is a type of case where surgery is indicated, for it is not yet necessarily assured that surgery is to be used in all cases of this condition.

There is, it seems to me, one definite clinical sign of this character, such sign being the existence of demonstrable stasis in the stomach. Where symptoms suggesting the possibility of duodenal ulcer are present in any case, the finding of stasis, that is, the presence of food remains or sarcinæ in the stomach at a period when the stomach, if mechanical conditions are normal, should contain no such residue, is a definite confirmation of diagnosis and an indication for operation.

It is true that this phenomenon of stasis may occur as the result of other conditions, as, for example, cancer of the stomach or ulcer of the stomach involving the pylorus, but operation is indicated in these cases as well as in that of duodenal ulcer. The rule may be stated as follows: Where stasis is demonstrable by the proper method of investigation, operation is indicated. Where with such a symptom cancer or gastric ulcer can be excluded, a diagnosis of duodenal ulcer is indicated.

I do not mean to say that reliance on this major sign interpreted with the above reservations can be depended upon for the absolute diagnosis or exclusion of duodenal ulcer. Cases of duodenal ulcer may exist in which this sign is not present at the time of investi-

[3] April 1 he reports that he has washed his stomach before breakfast twice a week, getting no residue. He is at work and has no symptoms.

[3] "The Pathology of the Living, and other essays," p. 24.

[4] The x-ray showed that the artificial opening is patent. Under medical treatment he gained 18 lb. in six weeks and was discharged free from symptoms although the stomach capacity remained 2,500 to 3,000 ccm.

gation. But if the sign is present, we can be assured of our diagnosis and proceed to operation.

If it is not present and we have other evidences of the ulcer, as blood in the feces, hypersecretion, subjective symptoms usually associated with this condition, we may or may not feel capable of a definite diagnosis, and even if assured, may not have indications for operation.

With the sign, we can be assured, with the reservations above noted. The presence of blood in the feces, together with this sign, gives additional confirmation of our diagnosis. The stasis which is found in duodenal ulcer may be either macroscopic or purely microscopic.

In most conditions of stasis as generally described a residue of food is found present in the stomach after a twelve hours' fast, sufficient to give a large macroscopic residue, recognizable as food.

In stasis from duodenal ulcer this condition may or may not exist. In some cases we find only a microscopic stasis. The quantity of residue in the stomach may amount to but 20 or 30 ccm., a quantity of fluid sometimes found in normal conditions, or it may amount to 100 to 200 ccm., but consist almost entirely of fluid and suggesting hypersecretion rather than stasis by its macroscopic appearance.

Under the microscope, however, a greater number of food particles will be found present than are ever present in the normal or in conditions other than stasis. Sarcinæ may be found in such conditions and are absolute evidence of stasis.

This microscopic stasis found in duodenal ulcer has not been given sufficient attention. I have seen many cases of this condition where a record of no stasis was made, and a doubt as to diagnosis expressed, because no macroscopic stasis was found, which showed good evidence of stasis by microscopic examination, and which proved to be cases of duodenal ulcer.

The recognition of microscopic stasis necessitates training. A few food particles may be found even in the residue obtained from the normal stomach. But the existence of a relatively greater amount of food or the sarcinæ can easily be determined by the expert.

It is a characteristic of some cases of duodenal ulcer that though they show such stasis on some examinations, they do not do so on all occasions. But by persistent study you can make your diagnosis. The claims that all cases with persistent symptoms of hypersecretion, of symptoms of relief, of gnawing in the stomach by food, of acid eructations or regurgitations, are cases of duodenal ulcer, must be set down as not proven. That these symptoms are frequently the associate of this condition is true. But all subjective symptoms are misleading in a subject with so highly organized a nervous system as the human subject. We must in these cases seek for definite objective signs, as stasis or hypersecretion as demonstrated by the examination of the stomach contents. This remark is intended for the surgeon as well as the general practitioner. That we shall never operate without these signs, or evidence of persistently recurring hemorrhages, I do not say, but we should go very slowly in such cases of suspected duodenal ulcer. Where the signs are present, we should operate.

DR. F. B. LUND: I well remember about ten years ago when Dr. Mayo came to Boston and read to us an interesting and stimulating paper on surgery of the stomach, and I cannot help realizing now how much our knowledge of the stomach surgery has advanced during that period and what a great share the work of Dr. Mayo and his associates has had in the making of modern progress in this department of surgery.

In 1899, I had the honor of reporting one of the earliest cases of perforating ulcer of the stomach to be successfully operated upon in Boston, and ever since then my interest in the subject has been great and continuous. When one has listened to a paper such as that of Dr. Mayo describing the experience based on such a very large number of cases, it is rather hard to have to admit that one is as yet but a beginner in the surgery of the stomach, but that is what I am compelled to do. In view of some of Dr. Shattuck's remarks, however, I think that it is only fair that I relate my own personal experience. When I began to perform gastro-enterostomy for ulcer of the stomach at the City Hospital, I could not say, as Moynihan has said some years ago, in reporting 100 successful cases without a death, "I made no mistakes, for fortunately others had made the mistakes for me," and I had to learn to do the operation rightly. I began by losing two cases from vicious circle, and of the twenty-three cases of gastro-enterostomy or excision for chronic ulcer of the stomach, including cases of hemorrhage, but not of perforation, which I have done up to date at the City Hospital, six died. Most of these were turned over to the surgeon very late, and much weakened by starvation and often hemorrhage. In the last five years, however, in private practice I have now performed 33 operations, including gastro-enterostomies and excisions for chronic ulcer of the stomach, with one death, or less than 3%, which is not such a bad record. I have done, in hospital and in private, 10 partial gastrectomies for carcinoma of the stomach with 2 deaths, or 20%. The first one, operated eight years ago, died because of faulty technic. The other, also an early case, died from injudicious attempt to remove a large amount of involved glands.

I have heard from 16 of the ulcer cases, 13 of whom are perfectly well in every way and all of whom are extremely grateful for restoration of health. Three are in fair condition and the remainder I have not been able to get in communication with.

In regard to operating upon these cases. Our patients at the City Hospital belong to the laboring class. In order to earn their living they are obliged to eat real food and do good, hard work. Undoubtedly, Dr. Shattuck's patients belong to the wealthy class and find it feasible to spend long periods at sanitariums at great expense and to undergo irksome and long-continued treatment with the stomach tube, meanwhile living in invalidism on a liquid diet. Working people who have families to support would almost rather take the risk of a very dangerous operation than undergo such treatment; in fact, they cannot do it. Personally, I feel that I would rather submit to one, two or even three laparotomies than to be obliged to have a stomach tube passed every other day. I believe, as a result of my own experience, that gastro-enterostomy is not a dangerous operation and I know that it restores to health and usefulness in the community a large number of miserable, dyspeptic invalids. The effects which I have seen in my own cases have been simply astonishing.

DR. JOHN T. BOTTOMLEY: The pleasure I have in taking part in the discussion of the evening is mingled with a feeling of great regret in that that skillful surgeon and splendid gentleman, my late chief and friend, Dr. John C. Munro, is not here with us to speak of the work at the Carney Hospital, so much of which was done by his hand. I stand in his place most unwillingly and most unworthily.

I have listened with interest to what our medical friends have said this evening. I realize fully that every case of dyspepsia, every case of gastric hemorrhage, every case of gastric ulcer, does not fall within the province of the surgeon. But I am equally sure that, were every internist to stand by the operating table of the surgeon and to see the living pathology of many gastric and duodenal diseases, he could not

but be convinced that medicine would be powerless to aid the sufferer, and that to many of the conditions surgery holds out the only hope of relief.

However, not all internists take the same ground as Dr. Shattuck. Let me read briefly from an article just published [5] by Dr. J. N. Hall, of Denver.

These are striking words, coming as they do from an internist:

"In deciding on the advisability of medical or surgical treatment in any given case of peptic ulcer which has attained a sufficient degree of severity to lead to the consideration of the latter method, we may state the advantages of medical treatment about as follows:

"1. Avoidance of immediate operative and anesthetic dangers.

"2. Avoidance of possible vicious circle, recurrence of jejunal ulcer, ventral hernia, post-operative adhesions, etc.

"Against these advantages we should set the following dangers:

"1. Likelihood of failure of medical treatment.

"2. At least an even chance that the patient will relapse if temporarily cured.

"3. Dangers of development of pyloric stenosis through presence of an active ulcer at that point, or spasm caused by its irritation, or cicatricial stenosis following its healing.

"4. Danger of hemorrhage or acute perforation.

"5. Danger of the development of cancer on the base of the ulcer (68% of the pylori excised by the Mayos for cancer showed origin in an ulcer, while 71% of those excised under the belief that they were cases of ulcer showed cancerous changes beginning [Wilson]).

"Nearly 10% of our patients operated on showed cancer.

"6. Danger of adhesions, which cripple the action of the stomach, obstruct the gall passages, produce serious pain and often require late operation.

"7. Dangers from a troop of late complications of slowly developing perforation, amongst which I have encountered peritonitis, subphrenic abscess, empyema, pyopneumothorax, pneumonia, perforation through the lung, septic pericarditis, mediastinitis, pancreatitis, suppurative processes about the liver and gall ducts, and general sepsis. Unfortunately many cases are reported under such headings without a recognition of the origin of the process in a peptic ulcer.

"8. The development of such a condition of anemia and malnutrition from the crippling of the digestive apparatus as to lead to neurasthenia, hysteria and various functional nervous diseases, or to pave the way for an easy and often fatal infection of the tubercle bacillus, pneumococcus, influenza bacillus, etc."

These words state the question fairly. That there is danger to the patient in the operation, no surgeon will deny. That there is necessarily great danger, Dr. Mayo's statistics disprove.

At the Carney we have operated on 45 cases of duodenal ulcer with 3 deaths. In these 3 deaths is included a death from hemorrhage and a death from abscess of the lung two months after operation. Reports from 25 of these cases have recently been received and 28 represent themselves as entirely well at periods of from two months to five years after operation.

Gastro-enterostomy for benign disease of the pylorus does not carry a high mortality. I have not had sufficient time to collect my statistics, but a hurried compilation of the last 100 gastro-enterostomies done at the Carney Hospital for benign disease of the stomach shows 8 deaths. Unfortunately I had not time to root out cases of benign gastric disease only. These 8 deaths included those which followed cases of perforation and also cases in which operation on other organs than the stomach were done at the same sitting.

I believe it important that the general practitioner should carry away from this meeting one thing at least, and that is, that the diagnosis of ulcer of the stomach or of the duodeneum can be made from the clinical history alone, and that chemical tests are only valuable corroborative signs.

## Book Reviews.

*The Prescribing of Spectacles.* By Archibald Stanley Percival, M.A., M.B., B.C. Cantab., Senior Surgeon, Northumberland and Durham Eye Infirmary. New York: William Wood & Co.

This little book of 160 pages is closely packed with facts and formulas. The author gives much space to mathematical optics as applied to detecting and correcting errors of refraction and muscular imbalance, but every part of the book is clear and interesting, and many suggestions are original and useful in prescribing spectacles. To read the book carefully means some work, but it is worth it.

*Practical Dietetics, with Reference to Diet in Disease.* By Alida Frances Pattee. Sixth edition, revised and enlarged. Mount Vernon, N. Y.: A. F. Pattee. 1910.

This sixth edition of a book that first appeared in 1903 may be taken as evidence that the work has met with fairly extensive appreciation and use. The introduction to the present volume shows in outline the requirements in dietetics of various state boards of examiners of nurses. Considerable matter has been added to the text of the original, and the caloric value of each recipe is stated. The book should continue its usefulness, not only as a practical treatise on dietetics for nurses, but as a domestic culinary guide for diet in health as well as in sickness.

*Transactions of the Fourth International Sanitary Conference of the American Republics.* Published and distributed under the auspices of the Pan-American Union, Washington, D. C. 1910.

This somewhat belated report of the proceedings of the Fourth International Sanitary Convention, held in San José, Costa Rica, Dec. 25, 1909, to to Jan. 3, 1910, contains complete account of the program of meetings and of the discussion at the several sessions. An appendix contains instructive reports of the various committees and of the delegations from the republics represented, namely, Chile, Colombia, Costa Rica, Cuba, El Salvador, Guatemala, Honduras, Mexico, Panama, Venezuela and the United States. The volume contains a large amount of valuable information, particularly with regard to tropical sanitation, hygiene and medical prophylaxis.

THE BOSTON
# Medical and Surgical Journal.

THURSDAY, APRIL 6, 1911

*A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.*

*All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.*

*Remittance should be made by money order, draft or registered letter payable to*

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

## LIMITATION OF THE UNDESIRABLE.

AN editorial on "Eugenics and Unemployment," in the issue of the *British Medical Journal* for March 25, discusses afresh a problem that is pressing for consideration in every civilized country. In England, the steady increase of the unemployable, and the steady decrease of the desirable, elements of population already constitute a condition of serious national economic importance. Efforts at remedy, it is pointed out, must be twofold: Encouragement of procreation among the fit, and prevention of propagation among the unfit. It is hard to say which is the more difficult to accomplish. The British income tax at present provides a certain exemption in proportion to the number of children under age in each family, but this measure would seem of rather negative value. No positive propositions of subsidization, such as we have recently noted in France and in Chicago, have as yet been made in England. The two methods suggested for limiting the undesirable are segregation and asexualization. The latter this editorial rejects as impracticable under the present status of public feeling. Segregation it considers more feasible, though enormously expensive and, as is suggested, fully as likely to lead to sexual crime, perversion and irresponsibility as asexualization by vasectomy. It is interesting that these conclusions are substantially the same as those recently reached by the Massachusetts Commission, upon whose report we commented in the issue of the JOURNAL for March 16.

The writer in the *British Medical Journal* considers that "the present position is due to the fact that by interference with the law of natural selection there have been brought about quite unnatural social conditions." It hardly seems that this is an entirely adequate explanation. Bad though conditions may be, they are probably not worse in degree, though different in kind, than what have often existed before. It is at least questionable whether the suggested measures, even if carried out, would materially relieve the situation. Probably in the long run natural process can be trusted to settle the problems of humanity as it has settled them for centuries, generally for the best, though of course vast personal suffering may be involved and civilizations perish in the accomplishment. Nevertheless, discussion of such questions from every point of view is eminently desirable, for man, by taking thought, may diminish the waste and destruction of natural process, even though he cannot hasten its operation.

## SOME PROPOSED ILLINOIS LEGISLATION.

THE monthly bulletin for March of the Illinois State Board of Health is "devcted to bills deemed of particular interest to the members of the medical profession," now pending before the legislature of that state. In view of much modern discussion of eugenics, two of these seem of special importance.

The first provides various amendments to the existing marriage laws of Illinois, which have been in force in their present form since 1874. One of these amendments requires that every application for a marriage license "shall state under oath whether either of the parties is an imbecile, epileptic, of unsound mind, or under conservatorship, and whether either applicant is or has been within five years an inmate of any insane asylum or poorhouse, and whether either of the contracting parties is afflicted with tuberculosis, syphilis or other transmissible diseases, and such application shall be accompanied by a certificate of a reputable practicing physician that the parties contemplating marriage are in sound bodily health and free from any recognizable indications of transmissible disease; and no such license shall be issued if it shall appear from such certificate, or otherwise, that either of the parties is deficient in any of the requirements enumerated." The intent of this proposed law seems good. Evasion of it would still be possible, and would probably occur; but the measure, which further provides a penalty for the fraudulent issuing of a health certificate, at least places the responsibility where it belongs, — with the medical profession.

"We must bear all. O hard condition,
Twin-born with greatness!"

This measure seems a wise and practicable step towards positive eugenics.

The second bill of importance to which we have referred is one relative to the sterilization of criminals, idiots and others. After a brief description of the operations of vasectomy and vaginal resection of the Fallopian tubes, the measure provides that all habitual criminals, idiots, feeble-minded, and imbeciles, inmates of public institutions, shall be examined by competent surgeons to determine their physical and mental condition and to decide whether it be improper and inadvisable to allow them to procreate. The result of such examination is to be reported "to the circuit court or any court of competent jurisdiction in and for the district from which such inmate, or inmates, has been committed to such institution or institutions. The court shall thereupon hear and determine the matter and if satisfied that the purposes of this act will be executed by such order shall adjudge that such operation shall be performed." Illegal sterilization of any person is made punishable by a fine not exceeding $1,000, or imprisonment for one year, or both.

Apart from the question whether Fallopian resection — in this act incorrectly termed oöphorectomy — is a really efficient means of sterilization, the advisability of such a measure is at least still open to discussion. Similar laws have already been adopted in California, Indiana and Connecticut, and thus far over 1,000 men and 20 women have been sterilized under their provisions. Except in the last-named state, public opinion in the conservative East seems at present generally opposed to such procedures, as it is in England. Segregation of defectives is the alternative, and though more expensive, is probably now more practicable and ultimately as efficacious. It is, nevertheless, desirable to observe such legislation as that proposed in Illinois, and to study the actual working of the experiment in those states by which it is made.

## THE PREVENTION OF VIOLENT DEATH FROM FIRE.

Naturally, all sorts of investigations are being made as to the causes of the appalling loss of life in the recent Washington Place fire in New York. It will eventually be found, no doubt, that the responsibility will have to be divided in several directions, but it seems probable that the chief cause was the lack of a fire drill among the factory employees. It appears that the means for extinguishing fire immediately at hand were not resorted to, and the developments of the investigations conducted by Fire Marshal Beers and the district attorney tend to show that the great loss of life was due not so much to lack of escapes as to extreme phases of panic.

Since this fire occurred, the value of the fire drill has again been demonstrated, in the case of two schools where there were fires: One a public school in the Bronx, and the other a large parochial school in Long Island City, Borough of Queens. In each instance the children marched out in perfect order, and the building was very promptly vacated. Some time ago a bill was introduced at Albany making fire drills obligatory in all large factories and stores, but it has never been made a law. Superintendent Maxwell, of the Board of Education, has suggested that employers of labor, particularly those who have lofts where girls work, should engage some of the younger public school principals, who are accustomed to managing the fire drills of large bodies of children, to give instructions in such drills. In speaking of this feature in his department, Mr. Maxwell says: "We have been insistent in carrying out the law which requires at least two fire drills in every month at each school. I receive reports as to the dates on which they are given and the time occupied in emptying the building completely, and if in any instance this requires more than three minutes, an inquiry is instituted. When it is considered that we have hundreds of schools with a capacity of more than 1,000 pupils, and many which have 1,500, 2,000 and even 3,000, while there is one with nearly 6,000, the importance of the subject cannot be overestimated. Since the institution of the drills there has never been a child injured in the slightest degree in a fire, though we have had many fires, two of them very serious. As a result of one of these, the building had to be rebuilt entirely; yet in this, as in all other cases, the children got out rapidly and in perfect order."

It has also been suggested that firemen who have been retired on pensions should be put in charge of the work of instituting fire drills. This latter suggestion may perhaps be the better one. H. F. J. Porter, an engineer who has been engaged for the past ten years in factory work, has pointed out that Mr. Maxwell's statement to the manufacturers may be misleading, in that it allows them to suppose that the school principals are educated along the lines of developing fire drills in buildings not constructed favorably for the purpose, and where the occupants are not of the

character of those with whom they have been accustomed to deal. Consequently, much harm might be done through having persons in charge who are not equipped to cope with existing conditions, upon whose drill the employer will depend, and find it at the critical moment inadequate and useless. Mr. Porter states that in every instance where he has installed fire drills in factories he has found it necessary to make one or more changes in the construction of the building in order that it might be adapted to a successful drill. He has always found it necessary also to install a fire alarm system which will notify the occupants exactly where the fire is located, as well as to develop and instruct a corps of fire fighters to extinguish the fire in its incipiency, if possible. The active work of instructing the operatives, he says, is a very simple matter.

The fund collected for the sufferers from the Washington Place fire having amounted to nearly $66,000, the Red Cross Emergency Relief Committee announced on March 31 that as this sum was deemed sufficient for its purposes, it would make no further appeal for contributions. At the same time it issued a statement which was in part as follows: "Every family has been visited and all emergent needs met. In a number of instances relief has been declined on the ground that the family resources were sufficient. The committee has respected and honored such self-reliance; nor has it obtruded relief when relatives or friends claimed a preferential right to bestow it. The gratifying and impressive feature of the contributions is the large number of small gifts, coming evidently from people of modest means, many of them apparently workmen, and the number of collective contributions from employees of this or that firm or company, not to speak of contributions from children." Since then the relief fund has increased to nearly $75,000.

## ASKLEPIOS AND THE GOOSE.

THE goose, and the cock, as is well known, were in antique times held sacred to Asklepios; and at various temples of that deity have been discovered statuettes representing a child carrying or strangling a goose. One of these statues from the temple at Cos is described in the recently discovered poems of Herondas. Another is mentioned by Pliny. In a recent number of the *Archeological Journal of Athens*, quoted in the *The Lancet* for March 11, M. Svoronos advances the ingenious theory that the goose in religious mythology symbolized pestilential pools and marshes, and that in these statuettes the child represents Ianiscos, the youngest son of Asklepios; and that when the boy is strangling the goose, the group typifies the healing of fevers by Asklepios and his family. In other groups, similarly, Asklepios himself, or one of his daughters, is depicted with a goose. Whether or no this interpretation be correct, it is an interesting contribution to the comparative study of ancient medical lore. Incidentally it may be noted that in his monograph on "Algiers as a Winter Resort," Dr. Alfred S. Gubb, of London, describes the discovery of a new temple and statue of Asklepios during recent excavations at Timgad. The worship of our patron deity was apparently as widely diffused as Greek civilization.

## A NOTABLE MEMORIAL MEETING.

IN the late afternoon of Friday, March 31, a memorial meeting was held under the auspices of the Bowditch Club for Dr. H. P. Bowditch and Dr. W. R. Brinckerhoff in the library of the Physiological Department of the Harvard Medical School. The Bowditch Club, founded some twelve years ago, was named in honor of Dr. Bowditch and has always been composed of younger men interested in the advancement of medicine through research. The club has continued to hold meetings during the intervening years, many of which Dr. Bowditch attended. Dr. Brinckerhoff before leaving Boston to take up his work in Honolulu was an active and always interested attendant at the dinners and meetings of the club. It was, therefore, fitting, that this special meeting should have been held under the auspices of this organization to do honor to two of its most distinguished members. It was also eminently appropriate that the meeting should have been held in a room closely identified with many of Dr. Bowditch's activities. The hour chosen was five o'clock, and as twilight came on toward the close of the exercises it seemed peculiarly to typify the feelings of the distinguished group of men invited by the club who had come to do honor to its two former members.

Dr. E. E. Southard, president of the Bowditch Club, after a few well-chosen introductory remarks, gave an admirable account of Brinckerhoff as a student and later as an investigator and teacher, a task he was peculiarly fitted to undertake since he was both a friend and a classmate of Brinckerhoff. Apart from his generally known traits of character and attainment, Dr. Southard drew attention to other less recog-

nized attributes which lent dignity to a peculiarly upright character. Following Dr. Southard, Dr. Walter B. Cannon, for many years closely associated with Dr. Bowditch both as student and teacher, later succeeding to his professorship, gave an account of Dr. Bowditch's long and productive life devoted very largely to the development of physiological science in its broadest aspects. Here, also, Dr. Cannon spoke from a close personal acquaintance with his former teacher which few others excepting his immediate contemporaries could have had. His remarks were full of feeling and appreciation of the high ideals and distinguished accomplishment which had attended Dr. Bowditch through his long period of activity.

Major Henry L. Higginson spoke informally and feelingly especially of Dr. Bowditch's war record, a period of his life of which he himself was not accustomed to speak except under mild compulsion. Mr. Higginson pointed out that excellent as he was as an officer and leader, his heart was not so much in the affairs of the war as in the prospect of establishing himself as an investigator, to which he proposed to devote his life, an object amply gratified in the succeeding years. It was remarkable, the speaker said, that so young a man — he was then twenty or twenty-one — should have had so clear a conception of his life work and should have been so favored as to have carried out the ideal he then set himself. President Eliot concluded the exercises by a touching personal tribute to Dr. Bowditch, to his character and to his capacity as a teacher and organizer. Coming as this tribute did from a man several years Dr. Bowditch's senior, who had been closely associated with him through many years of service to Harvard University and to the cause of education in general, the remarks made a profound impression upon every one present. President Eliot also spoke of Brinckerhoff, whom he naturally had known less well and in quite a different way. What he said of him did not occupy more than five minutes of time, but in it was compressed a tribute to his service to the community and to his devotion to the cause of productive research and high living which summarized in a way not soon to be forgotten the deep sense of loss which Brinckerhoff's death has occasioned.

The meeting was an impressive occasion from its simplicity, its informality and from the sincerity of the sentiments expressed regarding the double loss which Harvard University and the community at large has sustained.

## MEDICAL NOTES.

Birth of a Nineteenth Child. — It is reported from Chicago that on March 28, Mrs. John Adducci of that city gave birth to her nineteenth child. Mrs. Adducci is thirty-nine years old. Of the 19 children, 16 are living.

Award to Dr. Grenfell. — It is reported from New York that, on March 27, the Council of the Royal Geographical Society of England awarded to Dr. Wilfred T. Grenfell the Murchison bequest for the current year, in recognition of his work as an explorer in Labrador.

Memorial to Dr. Scott. — Report from Philadelphia states that the sum of $10,000 has been contributed by friends of the late Dr. J. Allison Scott, formerly adjunct professor of medicine at the University of Pennsylvania, for the establishment, in his memory, of a fellowship in medical research at that university.

Male and Female Infant Mortality. — A London physician is reported recently to have urged that especial measures be taken in England to check the mortality among male infants, in order to prevent the accumulation of an excess of superfluous women in that country. It is to be feared that this ungallant suggestion would be not only a piece of unjustifiable sex discrimination, but an attempted interference with normal process. As a matter of fact, the excess of females over males in any community is merely a biologic provision for extending natural selection.

Progress of the Plague Epidemics. — Report from Amsterdam states that there has recently been an outbreak of bubonic plague in the southeastern portion of the Dutch colony of Java. It is said that there have been already 350 cases of the disease in the island, with 224 deaths.

Report received at Washington, D. C., from the United States consul at Harbin states that although the epidemic of bubonic plague has abated considerably in that city and at Fuchiatien, China, the disease is still extensively prevalent throughout northern Manchuria. The United States consul at Shuanchengpu is said to estimate that there have been five thousand cases of plague in that city.

Interpretation of Pure Drug Laws. — Before the United States District Court at Boston last week, information was filed by the Assistant United States District Attorney against eight manufacturing firms in Massachusetts for

alleged violation of the pure food and drug laws. Before the same court a demurrer was also filed by another firm against information previously lodged against it. This firm contends that the laws in question have nothing to do with curative properties claimed for medicinal remedies, and cites a decision recently rendered in its favor by the District Court of Eastern Missouri. The demurrer has been taken under advisement and will probably be argued before the United States Supreme Court, whose decision will be important as determining future interpretation of the law with regard to proprietary medicines.

### BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, April 4, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 45, scarlatina 42, typhoid fever 4, measles 169, smallpox 0, tuberculosis 57.

The death-rate of the reported deaths for the week ending April 4, 1911, was 19.15.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, April 1, 1911, was 233, against 290 the corresponding week of last year, showing a decrease of 57 deaths, and making the death-rate for the week, 17.64. Of this number 116 were males and 117 were females; 228 were white and 5 colored; 141 were born in the United States, 90 in foreign countries and 2 unknown; 50 were of American parentage, 156 of foreign parentage and 27 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 46 cases and 4 deaths; scarlatina, 43 cases and 2 deaths; typhoid fever, 7 cases and 1 death; measles, 198 cases and 1 death; tuberculosis, 67 cases and 30 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 32, whooping cough 3, heart disease 24, bronchitis 5. There were 8 deaths from violent causes. The number of children who died under one year was 32; the number under five years, 50. The number of persons who died over sixty years of age was 77. The deaths in public institutions were 94.

Reappointment of School Physicians. — The Boston Board of Health last week recommended the reappointment of the present eighty members of the staff of public school physicians in this city, with an increase of salary to $500 each.

Graduating Exercises of Homœopathic Training School. — The graduating exercises of the Massachusetts Homœpathic Hospital Training School were held last week at the hospital building in Boston. Thirty nurses received diplomas.

Diphtheria in Winthrop. — The epidemic of diphtheria in Winthrop, Mass., to which we referred in last week's issue of the Journal, is still prevalent in that town. On April 1, 4 new cases of the disease were reported, making a total of 22 then known to exist. The Sunday-schools as well as the public day schools have been closed.

Prohibition of Public Drinking-Cups in Rhode Island. — It is reported from Providence, R. I., that on March 28, a bill prohibiting the use of common public drinking cups in that state was unanimously passed by the House of Representatives of the Rhode Island General Assembly. It is said that in Connecticut, also, the legislative abolition of the public drinking cup has been recommended by the State Board of Health.

Work and Needs of the Boston Dispensary. — In a letter on March 27 to the public press, the president of the board of managers of the Boston Dispensary called attention to the new plans and needs of this institution. During the year 1910 about 40,000 patients were treated at the Dispensary, and 20,000 visits made by district physicians. To enable the continuance and extension of this work, there is need of further money subscriptions, for which appeal is now made to the public.

Decline in the Therapeutic Use of Drugs. — It is well known that the use of drugs in all regular hospitals has steadily decreased during the past fifty years. Statistics recently published from the Boston Dispensary show that between 1854 and 1868 the apothecary of that institution filled an average of 2.1 prescriptions for each patient. In 1870, this figure had fallen to 1.32; in 1880, to 1.06; in 1900, to 0.89. In 1910 it was 0.81. During this time there has of course been a great increase in the use of massage, electricity and other mechanical methods of treatment.

Dartmouth Medical School Commencement. — The one hundred and thirteenth commencement of the Dartmouth Medical School was held with appropriate graduating exercises

at Hanover, N. H., on March 28. The degree of M.D. was conferred on eleven candidates. At the dinner subsequently given by the trustees to the graduates, addresses were made by Prof. C. C. Steward on "The Doctor and his Friends"; by Prof. C. E. Bolser on "The Doctor and the Patient"; by Dr. H. N. Kingsford on "The Doctor and his Profession"; and by Prof. E. J. Bartlett on "The Administration of the Hippocratic Oath."

NEW YORK.

A Centenarian. — Edward Van Voast, who came of good old Dutch and Revolutionary stock, died on March 31, at his home in Guilderland, Albany County, N. Y., at the reputed age of one hundred and seven years, having supposedly been born in Glenville, Schenectady County, N. Y., on Jan. 4, 1804. The illness which ended in his death is stated to have been the first of a serious character that he ever experienced. He was able to read without glasses, and used alcohol and tobacco in moderation.

Withdrawal of Russell Sage Institute from City Hospital. — As a result of the differences with Commissioner of Charities Drummond, the directors of the Russell Sage Institute of Pathology have now definitely decided to terminate the existing agreement with the Department of Public Charities and withdraw as pathologists of the City Hospital and City Home (Almshouse) on Blackwell's Island. This decision was reached at a meeting of the directors on March 27, when there were present Dr. D. Bryson Delavan, president of the institute; Drs. Simon Flexner and Theodore Janeway, and Prof. Graham Lusk, of Cornell University. The institute has been carrying on its work in the Strecker Memorial Laboratory at the City Hospital, and in leaving the island will relinquish some six thousand dollars a year which the city contributed toward its cost of maintenance. No announcement as to the field of its activities in the future has as yet been made.

Children's School Farm League. — A meeting in furtherance of the aims of the International Children's School Farm League was held at the Colony Club on March 29, when letters were read from Hon. Joseph H. Choate and from ex-President Roosevelt. The latter wrote that he hoped the day would come when there would be a school farm attached to every school and hospital in the city. Mrs. Henry Parsons, the founder and president of the league, who started the first school farm in New York, presided. Addresses were made by her son, Henry Griscom Parsons, secretary of the league and director of the department of school gardens for the training of teachers in New York University, and by Dr. John Winters Brannan, president of the board of trustees of Bellevue and Allied Hospitals, who, in commending the purposes of the league, said he could testify that the children's condition had materially improved from the work, while the teachers now had no discipline which was more heartily dreaded than the withholding of permission to go to the gardens.

Instruction in Practical Hygiene. — A comprehensive plan for the instruction in practical hygiene of teachers, as well as of the children in and out of school, elaborated by Dr. C. Ward Crampton, director of physical training of the Board of Education, has been put into effect in the public schools of New York. It is unnecessary to go into the various details of this, but the general idea is that the principles of hygiene should be inculcated throughout the pupil's entire course of study. In the beginning, Dr. Crampton states, the instruction should be by means of stories and illustrations from daily life. For the first three years it is needless to give reasons for the rules, but as the child progresses he will want to know why, and then may be told. The early lessons should inculcate habits of cleanliness of mind as well as body, attention particularly being given to the care of the teeth and to proper methods of study, play and rest, rather than to theoretical instruction in anatomy and physiology, which would be beyond the child's comprehension. After the third year textbooks should be used, but still the necessity of practicing the principles of hygiene, as outlined in the lessons, should be emphasized, and the tendency to try to cover too much ground in the class restrained. Only one or two points should be taken up at a time, and the pupil should be thoroughly grounded in these before passing on further. One of the principal needs is that the instruction should be continuous throughout the school, without breaks between classes, repetition or inconsistency of methods. The idea is to lead the pupil to adopt the principles of hygiene into his daily life, and this can be accomplished only by persistent effort. To assist in the carrying of the instruction received into practice, it is recommended that the larger pupils be provided with sets of rules to keep at home for constant reference.

5. Bishop, L. F. *The Nauheim Methods in the Management of Cardiac Diseases.*
6. Eising, E. H. *Bilateral Fibromyoma of the Broad Ligament.*
7. Mills, G. W. T. *Diagnostic Value of Tuberculin as Shown by Nineteen Autopsies.*
8. Arnold, W. F. *Prophylaxis against Hookworm Infection by Means of Efficient Shoes.*

1. Meltzer studied the effect of intramuscular injection of drugs in rabbits. He concludes that injection into the lumbar muscles is practically as effective as intravenous injection. The effect of injection into the gluteal muscles is inconstant and insignificant. The sacrospinal muscle is especially suitable; the absorption from this muscle is superior to that from the gluteal muscles and vastly superior to that from the subcutaneous tissue. In a limited number of cases of syphilis, salvarsan injected into this muscle has exerted a beneficial influence upon secondary and tertiary manifestations and upon the Wassermann reaction without causing pain or other serious ill effects. [L. D. C.]

8. Connell, in his review of the subject of subparietal rupture of the kidney, brings out the following essential points. The theory as to the cause that may explain a majority of the cases is that of Küster, in which the rupture is supposed to be due to hydraulic pressure acting through the full vessels and the pelvis and causing the organ to burst along lines radiating from the hilum towards the point of maximum impact against the lower rib. As regards symptoms, shock and collapse are often absent or but transitory and the lack of recognition of this fact has been the cause of mistaken diagnoses and delay in operative treatment in many cases. Pain is usually severe at the time of the injury. Its duration varies, but it is usually present and is followed by tenderness and a dull ache in the region of the ruptured organ. Rigidity of the muscles over the affected kidney is of great importance. Hematuria following trauma in the region of the kidney is not pathognomonic of injury to that organ, as the bleeding may originate in the bladder or urethra. There may be no differential sign or symptom between slight injury and complete rupture; therefore, it would seem advisable to expose the kidney and determine the extent of the injury in every case in which we can arrive at a probable diagnosis of injury to the kidney. This is probably the wisest cause. As it is impossible to separate the slight from the extensive injury, it is preferable to treat all cases as serious until they can be proved otherwise. Packing and draining or suture is a safer procedure than nephrectomy.

11. David states that typhoid bacilli are not found in the cerebrospinal fluid in uncomplicated cases of typhoid fever. Typhoid patients suffering the ordinary nervous manifestations, such as delirium, involuntary discharges and severe headaches, are not benefited by withdrawal of cerebrospinal fluid, although the fluid may be under increased pressure. In patients showing symptoms of meningitis, the spinal fluid may be sterile, but lumbar puncture and withdrawal of fluid has improved the clinical condition in a striking way in some cases. When typhoid fever patients show meningeal symptoms, such as rigidity of the neck, Kernig's sign, convulsions, strabismus or irregularity of the pupils, lumbar puncture should always be done and the fluid examined bacteriologically. [E. H. R.]

1. Kidd contributes an interesting article on some mediastinal affections. After first considering some of the rarer causes of mediastinal disease, he takes up the question of tuberculous mediastinal glands. He calls attention to the statement of d'Espine, of Geneva, that the presence of enlarged bronchial glands could be determined by auscultation over the spinous processes of the seventh cervical

and upper two or three dorsal vertebræ. Pectoriloquy or a bronchial quality of respiration in this situation he considers to be a certain sign of enlarged subtracheal glands. Kidd quotes Laennec and Gee that pectoriloquy or bronchial breathing is normally heard over this area, and his own investigations confirm this. Therefore he thinks that the views of d'Espine should be taken with considerable caution on this point.

5. Waterhouse presents the details of a case of sudden death in a child of eight months. Autopsy showed extensive hemorrhage into the suprarenal capsules as the evident cause of death. This he calls "suprarenal apoplexy." He briefly reviews the few previously reported cases of this condition. [J. B. H.]

7. Atkinson, A. G. *An Unusual Form of Perineal Hernia.*

1. Hertz gives a careful and systematic paper on dilated stomach; as to causes, he considers atony and pyloric obstruction. He briefly considers the symptoms, but goes into details of the various methods of investigation of the motor functions of the stomach, including percussion, inflation with gas, bismuth and the x-ray. In treatment for the atonic stomach he discusses the question of diet, drugs, massage and electricity. Gastro-enterostomy is strongly contra-indicated. The treatment of pyloric obstruction is gastro-enterostomy.

3. Cammidge, in a general article, discusses the cause and significance of chronic jaundice and goes over the symptoms and signs associated with this condition.

4. Chambers examined the urines of eight Marathon runners before and after the race. He comments on the the results found, which are in accord with other investigations along this line. [J. B. H.]

1. *Gibson, G. A. *Arterial Pressure.*
2. *Matthews, E. *Iodides in High Blood-Pressure and Arteriosclerosis.*
3. *Greig, D. M. *On Congenital High Scapula.*

1. Gibson, in a general article on arterial pressure, after first clearly defining the terms he is to use, discusses the influences at work which maintain this pressure. Among these he mentions the cardiac energy, condition of the arterial walls, resistance in the arterioles, and the character of the blood. He reviews the various methods and apparatuses in use to investigate and estimate the pressure and the possible fallacies in their use. He then considers arterial pressure in health and its variations according to circumstances and conditions, and last, in detail, arterial pressure in disease. He briefly considers arterial pressure in prognosis and the treatment of changes in pressure.

2. Matthews, discussing the mode of action of iodides in high blood-pressure, the application of iodides in high pressure, and arteriosclerosis, in so-called idiopathic high blood-pressure and in other conditions, comes to the following conclusions: (1) Iodides have a marked hypotensive action in high blood-pressure without arteriosclerosis; in advanced arteriosclerosis with high pressure, iodides have no hypotensive action. (2) Iodides act as vasodilators. (3) To produce a beneficial effect in hypertension, 10 gr. of potassium iodide should be the initial dose, and this should be rapidly increased if necessary. (4) Organic iodides contain too little iodine to be efficient.

3. Greig presents a paper, interesting chiefly on account of the rarity of the condition he describes, on congenital high scapula. There are numerous excellent illustrations and a full bibliography. [J. B. H.]

3. Azenfeld and Stock consider that there is an intimate relation between tuberculosis and certain eye diseases in young people. The relation is especially striking in dark ultra-ocular hemorrhages and the so-called retinitis proliferans. Also in tuberculous individuals there are frequently encountered perivascular changes in the retina, constituting a kind of periphlebitis. The point which seems uncertain is whether these areas are due to actual presence of the tubercle bacilli or are the result of toxins.

3. Flinzer, E. R. *Proteus Vulgaris. The Cause of a Subperichondral Rib Abscess.*
4. Hirohowa, W. *A Case of Prolapse of the Bladder in Pertussis.*
5. Fabrikant, M. B. *Double Empyema.*

1. The cases of appendicitis at the Göttingen Clinic occurring in the last fourteen years have been grouped and studied under the following headings.

(1) Early operation. (2) Intermediate stages, sick from three to five days. (3) Late stages, sick five days or more. Abscess formation. (4) Diffuse peritonitis. (5) Interval operation. (6) Fistula formation following appendicitis. (7) Unoperated cases. Many cases are reported under each heading. The conclusions arrived at do not differ in any way from the views which are generally held throughout this region.

2. The author reports 65 cases operated on under hedonal anesthesia, the drug being given intravenously. A .075% solution of hedonal in physiological saline is injected into a vein as is necessary through the operation to keep the patient unconscious. The operations performed were varied and included work on the head, chest, peritoneal cavity, perineum and extremities. The technic and apparatus are thoroughly described. There were two failures due to poor venous connections. There were no untoward results reported.

Their conclusions were as follows.

(1) Theoretically intravenous anesthesia is as safe as rectal or inhalation anesthesia.

(2) The injection of a .075% solution of hedonal in physiological saline intravenously will induce general anesthesia.

(3) The anesthesia can be continued over a longer period of time by the periodic injection of decreasing amounts of the solution.

(4) The dose necessary for anesthesia is much smaller than a toxic dose.

(5) The anesthesia is accompanied by good heart action and quiet rhythmic breathing.

(6) The introduction of the fluid does not markedly affect the blood pressure.

(7) By the intravenous injection of hedonal, the primary period of excitement is done away with.

(8) Too slow injection delays the appearance of anesthesia.

(9) In several cases, before complete anesthesia was produced, cessation of breathing took place due to too rapid injection of the fluid.

(10) Deep sleep is certain.

(11) During the post-operative period, headaches and vomiting are absolutely lacking.

(12) The kidneys are not affected.

(13) This method is indicated especially in operations on the head and neck and also on patients suffering from diseases of the kidneys, lungs and heart.

(14) In very strong individuals, and in cases where a deep sleep is desired, a previous injection of 3% hedonal by rectum is necessary. [J. B. S., Jr.]

11. Axhausen presents a series of interesting and valuable researches in problems associated with the surgery of bone injuries and diseases. He makes, first, some critical observations and new contributions on free bone transplantation. Next he considers the pathologic concept of halisteresis and bone dystrophy, concluding that pathologic changes of the internal secretions are ultimately responsible for disturbances of the quantitative and qualitative regulation of the bony structure, for the osteodystrophic processes. Third, he presents histologic and physiologic studies of the penetrating vascular canals of bone tissue, the so-called Volkmann's canals. Finally, he produces critical and experimental material on the genesis of arthritis deformans, especially on the significance of aseptic bone and cartilage necrosis. His work is admirably illustrated by microscopic and x-ray plates, and contains ample bibliographies.

14. Grune reports, with x-rays, a rare case of ossification of the coraco-clavicular ligaments, following a fall on the left shoulder.

17. Cahn reports a benign tumor of the rectum which he describes histologically as an epithelial heterotopia and discriminates from carcinoma in that the latter has a destructive active growth of modified epithelial cells and is principally cellular in composition, whereas the former is a passive inclusion of unmodified epithelial cells and consists chiefly of hyperplastic gland tissue and stroma. [This distinction seems at best academic. R. M. G.]

22. From an extensive series of animal experiments, the author concludes:

(*a*) That transplantation of the adrenal with a pedicle is followed by normal functional results of indefinite duration.

(*b*) That the transplanted adrenal fragment develops an entirely new and complete structure of cortex, medulla and capsule.

(*c*) That there is no tendency of the transplanted adrenal to malignant degeneration.

(*d*) That the medulla is to be regarded as a vital functional constituent of the organ.

(*e*) That such transplantation in man might become useful in the surgical treatment of Addison's disease.

23. Poulsen reports 19 cases of trigger finger and collects from the literature 64 others. From a study of these he concludes that the condition most frequently proceeds from tumors on the tendon or from narrowing of the tendon sheath, less often from articular or periarticular lesions. The origin of the tumor may be from direct trauma, from pressure or from congenital constriction of the sheath. [R. M. G.]

ANNALES DE L'INSTITUT PASTEUR.

JAN. 25, 1911.

1. *NICOLLE, C., AND CONSEIL, E. *Experimental Researches on Exanthematic Typhus Undertaken at the Pasteur Institute of Tunis during the Year 1910.* II. (To be continued.)
2. AYNAUD, M. *The Globulin of Man.*

4. MARGOULIES, M. *Action of Intra-Pleural Injections of Mellin's Food on the Progress of Certain Infections (Chicken Cholera in the Rabbit).*

1. In a long and complete article Nicolle and Conseil record the results of their experimentations on typhus fever during the past year. Their work is not finished in this number of the journal. They conclude that in the blood serum of convalescents and of animals cured of this disease there are bodies which can be used as a preventive against this disease. This can be used in epidemics and by people handling cases. These properties only exist in the serum for a short time after disappearance of the rash. [C. F., JR.]

BULLETTINO DELLE SCIENZE MEDICHE.

JANUARY, 1911.

1. *TASSINARI, S., AND MUGGIA, A. *The Prophylaxis of Eclampsia.*
2. *CAO, G. *The Opsonic Index in the Infections by Blastomycetes.*
3. *CAO, G. *A Pathogenic Sarcina.*
4. GUERRIERI, R. *The Mental State of a Woman Affected by a Tumor of the Right Orbital Cavity Compressing the Frontal Lobes of the Brain.*
5. *BELLEI, G. *Contribution to the Study of the Alimentary Intoxications Caused by the Proteus Vulgaris.*

1. Summarizing the records of the Bologna Maternity Asylum for the past fourteen years, the authors find that of 1,838 patients delivered during that time, 66 had albuminuria at some time during pregnancy or puerperium. Of these, only 3 had convulsions and only one died. These excellent results they attribute to careful clinical observation and prophylactic treatment of patients in pregnancy.

2. From a series of animal experiments, Cao reaches the following conclusions:

(*a*) That the serum of normal dogs, rabbits and guinea pigs has a natural opsonic power approximately equal towards pathogenic and towards non-pathogenic blastomycetes.

(*b*) That the same animals, after being vaccinated with cultures of pathogenic blastomycetes, killed by heat, yield a serum endowed with an opsonic power equal to that of normal animals towards non-pathogenic blastomycetes, but considerably exalted towards the pathogenic blastomycetes with which they were vaccinated.

(*c*) In vaccinated animals, the opsonic index is considerably higher towards the pathogenic blastomycetes which have served as antigen than towards non-pathogenic blastomycetes.

(*d*) Animals attacked by an experimental blastomycetic infection behave like the vaccinated animals, and the opsonic index of their serum is considerably higher towards the blastomycetic agents of the infection than towards non-pathogenic blastomycetes.

These results indicate that the opsonic properties of the blood react towards the blastomycetes as towards other infecting organisms.

3. Cao describes a new pathogenic sarcina, closely resembling S. *lutea*, which he isolated from the infected udder of a milch cow. He gives its cultural characteristics and reports a series of inoculation experiments which he performed with it upon guinea pigs, rabbits, rats, mice, dogs and fowls. He believes it probably a variety of the aerial S. *lutea*, which acquired virulence from sojourn in manure, or by passage through the intestine of cockroaches, of dung-eating beetles or of other insects, or by sojourn in putrefying organic substances.

5. By bacteriologic examination of some sausages, supposed to have caused an epidemic of ptomaine poisoning, Bellei found the following organisms: bacillus mesentericus vulgatus, bacterium coli, proteus vulgaris. Animals inoculated with pieces of meat taken from these sausages died of lesions caused exclusively by the proteus vulgaris. The author, therefore, believes this organism to have been the causative agent of the epidemic in question. [R. M. G.]

FEBRUARY, 1911.

1. *GHILLINI, C. *Operations Performed in the United States. Surgery and Orthopedics in America.*
2. ZAMBONI, G. *Typhoid Fever in Bologna and in the Pediatric Clinic in the Decennium, 1900–1909.*

1. Ghillini reports 2 cases on which he operated at the time of his visit to the United States in the spring of 1908, and speaks most enthusiastically and interestingly of his experiences and impressions of orthopedics and surgery in this country. He considers the technic of American surgeons excellent, but says that "their great operative ability is accompanied by a scientific deficiency, which depends on the brevity of their studies." He describes at some length the Mount Sinai Hospital, several orthopedic institutions, and the New York Post-Graduate Medical School and Hospital. The points which especially excited his admiration were:

(*a*) The provisional medical license to strangers, in Colorado, for the exercise of their profession.

(*b*) The opportunity for all reputable surgeons to treat their patients at the hospital in Denver.

(*c*) The combination of medical school and hospital. [R. M. G.]

## Miscellany.

### THE CHOLERA EPIDEMIC AT MADEIRA.

IN several issues of the JOURNAL during the past winter we described the progress of the epidemic of Asiatic cholera in Madeira. No new cases of the disease have been reported in the island since the first of March, and the epidemic is, therefore, now officially declared at an end. *The Lancet* for March 18 contains completed statistics of the outbreak. The first cases are believed to have occurred about the middle of October; and in the four and one-half months during which the epidemic prevailed, there were reported 1,769 cases with 556 deaths. In 75% of the cases the onset was acute; in 25% it was gradual. Ten per cent of those attacked were known to be habitual alcoholics, though it does not appear that alcoholism is more a predisposing factor in this infection than in any other. The duration of the disease was from three to ten days. In a few cases the acute attack was succeeded by a chronic typhoidal condition. Numerous healthy cholera carriers were observed. With proper sanitation and quarantine, however, it would seem that the disease should be as controllable and preventable as typhoid fever.

### DISTRIBUTION OF IRISH-BORN POPULATION.

THE population of Ireland has been steadily decreasing for the past fifty years at an average rate of about 7.4% in each decade. This decrease has been largely by emigration to the United States, since the birth-rate in the island has remained relatively high and continues to exceed the death-rate. In 1900 there were in the United States 1,619,449 persons born in Ireland, of whom 425,553 were in New York state and 249,916 in Massachusetts. The ex-

act figures of our 1910 census are not yet available on this point, but it is estimated that at present there are in this country approximately 2,000,000 persons born in Ireland. This estimate, of course, does not include persons born here of Irish parentage. Were these added, there would probably be more persons of Irish extraction in the United States than in Ireland. Boston today has a larger Irish population than any other city in the world except Dublin. These figures afford an interesting modern instance of race migration.

## WORK OF THE ROCKEFELLER HOOKWORM COMMISSION.

A REPORT by the Rockefeller Hookworm Commission states that the existence of uncinariasis has now been demonstrated in Alabama, Arkansas, California, Florida, Georgia, Kentucky, Louisiana, Mississippi, Nevada, North Carolina, Oklahoma, South Carolina, Tennessee, Texas and Virginia. The disease is said to be most extensive in the Carolinas and in Georgia. In 39 counties of the latter state from 40 to 80% of the school-children are estimated to be infected. In Georgia 17,775 children have been examined and 6,000 treated for hookworm. The commission has also begun to distribute through the southern states literature explaining to the people the nature of uncinariasis and the means of its prevention and cure.

## SOCIETY NOTICE.

AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION. — The annual meeting of the American Medico-Psychological Association will be held June 19, 20, 21 and 22, 1911, at the Brown Palace Hotel, Denver, Colo.

## RECENT DEATHS.

DR. JOHN W. VAN DRUSEN, of Brooklyn, N. Y., died on March 28. He was forty-nine years of age, and a native of Jersey City, N. J. He was graduated from the medical department of New York University in 1884, and at the time of his death was attending physician to the Kingston Avenue Hospital.

DR. ISAAC S. CHAMER, of Flemington, N. J., died on March 25, at the age of seventy-eight years. He was born at Changewater, and was graduated from the College of Physicians and Surgeons, New York, in 1854. In 1889 he was surrogate of Hunterdon County.

DR. CHARLES HENRY LEWIS, a prominent practitioner of New York, died suddenly from cerebral apoplexy on March 31, in the fifty-third year of his age. He was born at Naugatuck, Conn., and was graduated from Yale University in 1882 and from Bellevue Hospital Medical College in 1884. He then served as interne at St. Vincent's Hospital, New York. Dr. Lewis was one of the charter members of the Medical Association of the Greater City of New York, and at the time of his death was visiting physician to St. Vincent's Hospital and president of its medical board. He was also visiting physician to the Columbus Hospital.

DR. SIMON M. BRAININ, of New York, died on March 31. He was a graduate of the University of Dorpat in the year 1881.

REYNOLD JAMES MCCORMACK, M.D., M.M.S.S., died at Roxbury, Mass., on March 29, aged forty-eight years. He was born in Prince Edward Island, Canada. After graduating from St. Dunstan's College, he studied medicine at the University of New York, from which he received the degree of M.D. in 1886. He first settled in Salem, Mass., but in 1893 removed thence to Roxbury, where he continued to practice until his death. For many years he was attending physician to the Boston Nursery and Hospital for Blind Babies. He was a Fellow of The Massachusetts Medical Society, a member of the Norfolk District Medical Society and of the New England Alumni Association of New York Medical Colleges. He is survived by his widow.

DR. WILLIAM PARK, who died last week at Fredonia, N. Y., was born in Boston in 1839. He had practiced dentistry for fifteen years in New York City and for thirty-five years at Fredonia.

HENRY LYMAN SHAW, M.D., M.M.S.S., died in Boston, April 2, 1911, aged seventy-three years.

FOSTER, JAMES MILTON, M.D., M.M.S.S., died in Wilbraham, March 17, 1911, aged eighty-two years.

## BOOKS AND PAMPHLETS RECEIVED.

State Board Questions and Answers. By R. Max Goepp, M.D. Second edition. W. B. Saunders Co.

Diseases of the Nose, Throat and Ear. By William Lincoln Ballenger, M.D. Lea & Febiger.

Encyclopédie Médicale. Redaction et Administration. Paris.

On Percussion and on Percussion of the Kidneys. By Otto Larch, A.M., M.D. Reprint.

La Prostatectomie Transvésicale. Paris. Reprint.

The Making of a Surgeon. By George W. Guthrie, M.D. Wilkesbarre, Pa. Reprint.

Diuretin Knoll. Knoll & Co.

Report of the Commission on the Increase of Criminals, Mental Defectives, Epileptics and Degenerates. January, 1911.

National Association for the Study and Prevention of Tuberculosis. Sixth Annual Meeting, Washington, D. C.

City of Boston, Statistics Department. Special Publications No. 17. Receipts and Expenditures of Ordinary Revenue. 1905-6.

City of Boston, Statistics Department. Referenda in Massachusetts and Boston. By Dr. Edward M. Hartwell.

# AN ANALYSIS OF FORTY-SIX CASES OF PROSTATECTOMY.

BY LINCOLN DAVIS, M.D., BOSTON.

THE brilliant work of the modern pioneers in the field of prostatic surgery has tended to standardize certain definite operative measures, each of which in the hands of its exponents has yielded remarkably successful results. The successes of the leaders in this line of work are both an incentive and a deterrent to newcomers in the field; the high standard established is at the same time alluring and discouraging; yet if the basic operative principles are sound, and are intelligently applied, they should yield, even in the hands of the less experienced and expert, at least reasonably good results.

This report is offered with the object of laying bare the experiences and results in a relatively small number of cases unselected by the operator in a general hospital service. The series of 46 cases represents the entire experience of the writer at the Massachusetts General Hospital; the cases were turned over to him through the courtesy of the members of the visiting staff, to whom grateful acknowledgment is hereby made. The cases reported do not by any means represent the total number of such operations performed at the hospital during this period, but represent from approximately one third to one half of the total cases. There was no selection of cases as to whether favorable or unfavorable; they were taken as they came. Only one case of benign prostatic enlargement was refused operation, and in this case death resulted from uremia within a week of entrance. Two or three cases of hopeless malignant disease of the prostate were not operated upon, in none of which was there complete obstruction.

Of the 46 cases, 36 were of benign hypertrophy, 9 cancer, and 1 tuberculosis. The proportion of the malignant cases seems very high, slightly exceeding the ratio found by Young in his large series of cases.

### CASES OF SIMPLE HYPERTROPHY.

There were 36 of these. The ages of the patients varied from forty-seven to eighty-eight. There were 3 cases under fifty, 4 between fifty and sixty, 16 between sixty and seventy, 10 between seventy and eighty, 3 above eighty. Thirty-four patients were, or had been, married; 2 were single. Only 7 admitted having had gonorrhea.

### GENERAL CONDITION BEFORE OPERATION.

This varied greatly; some were strong and vigorous without other signs of disease, others showed varying degrees of senility or decrepitude, such as arteriosclerosis, irregularity and feebleness of heart action, edema of feet, râles in chest; a few were distinctly uremic or septic, as evidenced by foul scanty urine, fever, dry skin, coated tongue, and mild delirium at night. In the latter cases (Nos. 11, 15, 22, 35, 40), also when the bladder had been greatly over-distended, preliminary treatment was resorted to, consisting of constant urethral catheter drainage, with irrigation of the bladder, salt solution enemata, ingestion of large quantities of water and urotropin. After ten days or two weeks of this treatment, improvement resulted in every case, and the condition seemed sufficiently good to warrant operation. In the great majority of cases this preliminary treatment was not considered necessary, and operation was performed within a few days of admission.

### DEGREE OF URINARY OBSTRUCTION.

In 30 cases there was retention of urine before operation. Twenty-five of these patients were absolutely unable to void and had to be catheterized; 5, while not having resorted to the use of the catheter, were merely dribbling from an overflow bladder. One patient had depended entirely upon the catheter for fifteen years, one for eight years and another for five years. Six patients were still able to pass more or less urine voluntarily. Two of these had used the catheter regularly for a number of years and had from 10 to 12 oz. of residual urine. One patient had a residual of only about 4 oz. at the time of operation, although he had had two previous attacks of retention requiring catheterization. In one case there had been a previous attack of retention relieved by the catheter, amount of residual at the time of operation not recorded. One patient had only 3 oz. of residual with frequency and difficulty of micturition for years. One patient (No. 1) had practically no symptoms of obstruction (the amount of residual is not recorded), the operation was done under a misapprehension, the prostate was considered to be malignant from the feel and cystoscopic appearance, and the source of hematuria; it proved to be a moderately enlarged gland showing merely glandular hypertrophy without evidence of malignancy.

### PRECEDING OPERATIONS.

One patient had had a suprapubic removal of a third lobe, another a partial perineal prostatectomy, both without relief. Two patients had had stones removed at previous operations. Two had had perineal section for drainage. In one case a papilloma had been removed by suprapubic cystotomy. In one case orchidectomy had been done for abscess of testicle. One patient had an extensive diverticulum which was drained suprapubically preliminary to suprapubic prostatectomy.

### CYSTOSCOPY.

Of the 36 cases of benign enlargement, in only 17 are cystoscopic examinations recorded. In a few, such examinations were made, but the records are missing. In a few cases, cystoscopy was impossible either on account of bleeding, pain or difficulty in passing the instrument. In a considerable number of cases it must be ad-

mitted this important examination was neglected. There is no doubt in my mind of the value of preliminary cystoscopic examination before prostatectomy, especially before perineal prostatectomy. In this way invaluable knowledge as to the shape, contour and intravesical proportions of the prostate, the presence of a median lobe or bar, the presence and size of stones, new growths and diverticulæ, can be gained. The estimation of the size and intravesical shape of the prostate is, I think, one of the most difficult things to determine in cystoscopy, and requires considerable experience checked by operative demonstration. It is a distinct advantage to the operator to have made the cystoscopic examination personally; the mental picture of the intravesical growth of the prostate, which it is hard to set down in words, gives one a grasp of the situation in undertaking a perineal prostatectomy which is a real if intangible asset.

Whether or not there has been a preliminary cystoscopic examination, a thorough digital exploration of the bladder should be made in every case, — before enucleation of the prostate in suprapubic cases, and after in perineal cases. This is essential and invaluable and will save many costly errors if always followed. In the elevated lithotomy position, so strongly insisted upon by Proust, and Young, for perineal prostatectomy, a movable stone in the bladder is apt to fall back into the fundus, and may easily be out of reach of the examining finger, or it may lie in a pouch; hence it is not safe to rely entirely upon digital examination for knowledge of this condition in such operations. A careful preliminary cystoscopic examination relieves one of anxiety on this score.

### CHOICE OF OPERATION.

I began by doing suprapubic prostatectomy. The first operation was done in February, 1906. The first few cases were highly satisfactory; on the fourth case there was considerable postoperative and secondary bleeding, which could not be controlled, and only stopped when the patient was nearly exsanguinated. The patient eventually made a complete recovery with an excellent result. This case, however, somewhat dampened my ardor for the suprapubic operation, and the next two cases, which were both fatal, one from shock and hemorrhage, the other from uremia, completed my distrust. I then took up the dissecting perineal method, the first case being done in May, 1908, and have continued to use this method since almost exclusively. I consider it the method of choice in the ordinary case, reserving the suprapubic method for the exceptional cases of enormous hypertrophy, or when the condition is complicated by the presence of a diverticulum, a tumor or a stone of great size, or an adherent stone, or when the bladder is filled with blood from an actively bleeding prostate.

My prime reason for preferring the open perineal prostatectomy operation to the suprapubic is that it is safer as far as life is concerned. This has been amply proved, I think.

The suprapubic enucleation has its strong points; it is a quick method, and easy of performance, except when the gland is small, fibrous and adherent, when it may be impossible, as admitted even by Freyer. The end results are excellent; if the patient survives the operation, he is almost sure of a good functional result. There is little danger of injury to the rectum or of incontinence, the bugbears of the perineal route; sexual power is often retained, although the ejaculatory ducts, I believe, are seldom spared. On the other hand, there is considerable shock, and often hemorrhage, which is difficult to control; also liability to sepsis and urinary infiltration.

The chief advantages of the open perineal method are that the operation can be done under the control of the eye, shock is markedly less, hemorrhage can be more effectively controlled, sepsis is usually inconsequential, fibrous or adherent prostates can be removed by morcellement. Sexual power can be preserved in a fair proportion of cases. The convalescence is quicker and more comfortable; the functional results are as good in the hands of the elect.

The technic is difficult and must be mastered to avoid two sequelæ of dire consequence, — incontinence and injury to the rectum. If the technical details of the Young operation are fully grasped, these accidents will be rare. The Young operation is not a total prostatectomy as is the suprapubic, a shell of prostatic tissue is left just inside the capsule, also surrounding the urethra and ejaculatory ducts. It has occurred to me that there might be a new growth of tissue from this source, giving rise to obstruction in the future. I have never heard of such a contingency, however; my own cases are for the most part too recent to give convincing data on this point.

The finger enucleation through a median perineal section is a method with which I have had no personal experience. It is open to many of the same objections as the suprapubic method, viz., blindness and inadequate control of hemorrhage, likewise to liability of injury to the rectum, and incontinence, the bugbears of any perineal operation. It is a quick method and seems to have given excellent results in the hands of its advocates. The mortality is low. I must, however, believe it is subject to many bad sequelæ.

### ANESTHESIA.

During the last year I have employed spinal anesthesia administered by Dr. Freeman Allen in 9 cases, 2 suprapubic and 7 perineal. The method has been highly successful, and I believe it to be a life-saving measure for these old and enfeebled patients. The only objection to it is that the Trendelenburg position cannot be maintained in the early stages of the operation, or at least only to a slight extent. This position though a help is not essential. The advantages of spinal anesthesia in my opinion far outweigh this one objection.

OPERATIVE TECHNIC.

*Suprapubic cases.* — Digital enucleation of the whole gland with the forefinger of the opposite hand in the rectum has been the method employed in all cases, with post-operative drainage through a suprapubic tube, later supplemented, as a rule, by urethral catheter drainage. In several cases gauze was packed into the cavity left by the enucleation for the control of hemorrhage, although this measure has been resorted to with some reluctance. In 2 cases the prostate was approached through a transperitoneal cystotomy wound; once after an unsuccessful attempt to excise an extensive diverticulum of the bladder, and once to give a better approach to a large vesical tumor which proved to be of prostatic origin. In both these cases the results were excellent, but the method is unnecessarily hazardous and I do not advocate it.

*Perineal cases.* — The method employed in these cases has been as close an imitation as might be of the technic so perfectly portrayed and demonstrated by Dr. H. H. Young. The only respect in which I have ventured to depart from his method has been in regard to the saving of that median portion of the gland which contains the ejaculatory ducts. I have not hesitated to sacrifice this median bridge of tissue in certain cases in order to get a better approach to the suburethral portion, and allow of a submucous enucleation of a sessile third lobe or bar. Pedunculated median lobes have been grasped and pulled down into the urethra and excised, although this procedure is fraught with some danger from hemorrhage. Persistent bleeding from this source in a private case was, I am convinced, a contributing cause of the fatal result which ensued. Care should be taken in such cases to ligate, crush or cauterize the pedicle; if the pedicle is large, the mass can often be enucleated from below without injury to the mucous membrane, which, of course, obviates the danger of bleeding into the bladder; any bleeding which may occur will be external, and can be controlled by packing. In dealing with median lobes and bars by the suburethral method, I have found it advantageous to replace the tractor by the forefinger of the left hand passed well into the bladder, as the sense of touch is of immense value in determining how much and where tissue should be removed.

Young makes a great point of the preservation of the ejaculatory ducts, arguing that it permits of the retention of sexual power, and obviates the danger of epididymitis. There can be no question but that preservation of the ejaculatory ducts is necessary to the retention of procreative power, a matter of little importance as a rule in these cases; but that the power of erection, a more important though by no means dominant desideratum, has any relation to the integrity of the ducts is open to doubt. The power of erection depends upon the integrity of the nerve supply; this may be injuriously affected possibly by the division of the main branch of the pudic nerve in a too wide dissection of the perineum, or more probably by section of the small sympathetic fibres, cavernous nerves, which run forward to the corpora cavernosa from the prostatic plexus, during the process of exposing and clearing the prostatic capsule. Blunt dissection is the key to the avoidance of this mischance.

That injury to the ducts does not affect the power of erection has been amply proved by the numerous cases of complete removal of the prostate gland, including the entire prostatic urethra, and ejaculatory ducts, by the suprapubic route, with subsequent retention of that power.

As to the avoidance of subsequent epididymitis by preservation of the ejaculatory ducts, I have been disappointed by the results in my own cases in which this was done. The occurrence of epididymitis, which will be taken up later, has been so frequent that the matter of ligature of the vas deferens in the scrotum as a routine measure is now under consideration

MORTALITY.

*Suprapubic cases.* — There have been 12 cases of benign hypertrophied prostates removed by the suprapubic route with 2 deaths, a mortality of 16⅔%, a very high rate. In one of the fatal cases (No. 8), operation should never have been attempted, as the patient was uremic and demented before operation, and just faded away after operation, refusing all nourishment and dying of inanition and uremia on the tenth day. In the other case (No. 11), death was directly due to operative shock, and hemorrhage.

*Perineal cases.* — There have been 24 perineal prostatectomies for benign hypertrophy with 2 fatalities, a mortality of 8⅓%. At the time this paper was compiled there had been only one fatal case, giving a mortality of about 4%, but while awaiting publication another case was taken on, which has since resulted fatally, thereby doubling the percentage. This was the case (No. 45) of a man sixty years old who had used a catheter for a year; his general condition seemed excellent. Two small lobes were enucleated by the usual technic under spinal anesthesia. The immediate convalescence was uneventful except for a moderate bronchitis. At the end of ten days he was up and beginning to walk about, with control of urination, some urine coming through the penile urethra. Two weeks after operation lobar pneumonia set in, involving the two lower lobes of the right side. In an access of sudden delirium the patient jumped out of a window into the snow. This exposure was followed by empyema. Two quarts of pus were drained from the right pleural cavity. In spite of efficient drainage the patient gradually failed, the left lung filled up with edema, and he died on the thirtieth day after operation. Autopsy showed unexpanded right lung, bronchopneumonia of left lung, the genito-urinary tract was in excellent condition, there was still an unhealed perineal sinus. The cause of death was wholly pulmonary.

The other fatal case (No. 17) was that of a man seventy-nine years of age who was operated on March 15, 1909. A tough fibrous and in-

flammatory gland was enucleated with considerable difficulty through the perineum, the prostatic urethra was slightly torn, the immediate convalescence was good, the patient regained control of urination on the ninth day. Although most of the urine came through the perineum, the wound was clean and granulating. He had been sitting up daily, was perfectly comfortable and the temperature was normal. On the thirteenth day the temperature shot up, and beginning facial erysipelas was discovered. Starting from the nose, this spread over his face and neck, was accompanied by high temperature and great prostration, necessitating his keeping in bed. Although the erysipelas subsided, hypostatic pneumonia developed and he died on the twentieth day after operation.

Including malignant cases, there have been 15 suprapubic prostatectomies with 2 deaths, mortality 13⅓%. There have been a total of 31 perineal prostatectomies with 2 deaths, a mortality of 6¼%.

The mortality for the whole series of 46 cases is 4, or 8.7%.

### COMPLICATIONS DURING CONVALESCENCE.

*Suprapubic cases.* — Of the 10 patients out of 12 who survived the operation, the convalescence was uncomplicated in 6. Three suffered from epididymitis, 30%; in one case in which there was severe and long-continued bleeding, there was double epididymitis. In no other case which survived was post-operative bleeding of consequence. In one case (No. 41) there was complete post-operative closure of the bladder outlet, from flap formation, a complication first described, I think, by Dr. A. T. Cabot. This required secondary operation and renewal of catheter drainage. The patient was removed from the hospital on the forty-second day against medical advice, with the suprapubic wound still open. He has not been heard from since. In all the other cases the wounds were closed at the time of discharge, and in all save one satisfactory interval urination was established. In this case (No. 37) there had been a previous partial perineal prostatectomy by another operator, and almost complete incontinence followed removal of the remaining portions of the gland by the suprapubic route. The first operation had doubtless injured the external sphincter, and the second the internal sphincter. The shortest stay in the hospital after operation was eighteen days; the longest, forty-six days. The average stay in the hospital after operation was thirty-three and one-half days.

*Perineal cases.* — Of the 22 patients who survived perineal prostatectomy, secondary hemorrhage occurred once. This occurred (Case No. 19) on the second day, following removal of the gauze packs; it was severe but brief, being completely controlled by repacking the wound. Since then the gauze wicks have not been removed for forty-eight hours, with no further trouble on this score.

Epididymitis occurred in 8 cases, 33%; in 2 of these after discharge from the hospital. In 3 cases it was severe, going on to abscess formation, requiring incision and drainage. Although the perineal wounds were undoubtedly infected in all these cases of epididymitis, this infection did not of itself seem to amount to anything in any case.

In 4 cases (Nos. 15, 16, 20 and 43) there was retention of urine after removal of the tubes, requiring drainage for a longer time; this was undoubtedly due to swelling and possibly infection, as there was epididymitis present in 3 out of 4 cases. This retention was transient in all cases, but was a disquieting complication while it lasted.

In none of these 24 cases was there any injury to the rectum.

As a rule, immediately after removal of the perineal tube there was interval urination through the wound with control. In some cases this function was considerably delayed, sometimes for a week, rarely for two or three weeks. Interval penile urination was established on the third day in two cases; this was the quickest. As a rule, it occurred at the end of about two weeks, in a few cases it was greatly delayed.

In 16 cases at the time of discharge there was normal penile urination: in only 2 of these were the wounds completely healed. In most cases there was still a small granulating area which in several instances leaked a few drops of urine at the time of urination.

In 6 cases a large part of the urine was voided through the perineal wound at the time of discharge; in 2 cases all the urine was so voided; there was, however, control of the act in all.

The shortest stay in the hospital after operation was thirteen days, the longest seventy-three days, the average was twenty-seven and one-half days. The patient who left on the thirteenth day (No. 32) had normal urination with a small granulating perineal wound without leakage, showing the possibilities of the operation in favorable cases.

### END RESULTS.

It is by the end results that the value of an operation should be judged.

*Suprapubic cases.* — Of the 12 patients operated on by the upper route, 2 died. One case (No. 41) already referred to, in which the complication of closure of the bladder outlet during convalescence occurred, requiring a secondary operation, has not been traced since discharge. There is no reason why the final result should not have been satisfactory, however. In one case (No. 37) in which the suprapubic operation followed an unsuccessful partial perineal prostatectomy, by another surgeon, the incontinence which followed unquestionably would not have occurred if the external sphincter had not been injured in the first operation. In the eight remaining cases the functional results were excellent. Two patients have died since leaving the hospital, one three months afterwards of pneumonia, one four years later of new growth of bladder; in neither were

there any symptoms on the part of the prostate. Six patients have recently reported themselves alive and well without urinary symptoms.

Data as to amount of residual urine are unfortunately meager; several of the patients lived at considerable distances and were able to report only by letter. In 6 cases in which it is recorded, the highest amount was 1½ oz. in a man who previous to operation had lived a catheter life for fifteen years; in the other 5 cases, it was less than 1 oz.

As to sexual power, data is still scantier. Two are known to have retained it; in one patient who underwent both operations it was lost.

*Perineal cases.* — Of the 24 patients operated on by the perineal route, 2 died; all the others have recently reported either in person or by letter. All have been relieved of obstruction. In 20 cases the amount of residual has been recorded; in only 2 has it exceeded 1 oz., and in those 2 it was as low or lower than that when last measured. In the 3 cases in which the amount has not been measured, there were no symptoms of obstruction. In two patients in whom the residual amounted to 3 and 8 oz. respectively, at the time of discharge, the bladder recovered its tone very shortly, and within a month or two, the residual had dropped to less than 1 oz. and 1 dram respectively.

There has been complete and satisfactory sphincteric control of the bladder in all but 2 cases. One patient (No. 10), the first one operated on by the perineal method, can hold urine only about one-half hour, when he begins to dribble; he wears a urinal. He had a perineal section previous to the prostatectomy which may have had something to do with the poor muscular control. Such a case could undoubtedly be much benefited by regular treatment, of which he has had none.

In one recent case a man of seventy-seven (No. 21) there is said to be occasionally slight leakage during the day when walking about, although I have seen no evidence of it on the three occasions on which I have examined him; none at night.

As previously stated, the great majority of patients left the hospital with perineal wounds not entirely healed; in 6 a considerable portion of the urine was voided through them. In all but 3 cases the wounds completely closed shortly after leaving the hospital; I am unable to give figures as to just when this occurred. In one case it was six months before the sinus finally closed.

In 2 cases, fistulæ have persisted. In one case (No. 23) the perineal fistula, which had persisted for a year after operation, causing the occasional leakage of a few drops during the act of micturition, was curetted out, but has recently reopened; it causes but slight inconvenience and the patient is not inclined to have anything further done. In the other case a minute fistula has persisted for one year, the patient regards it as of little consequence and has had no medical attention.

In one case (No. 42), the patient was seen six weeks after leaving the hospital; at this time all the urine was passed through the perineal wound, although at the time of discharge it was passed naturally. With considerable difficulty sounds were passed and the bladder irrigated. From this moment all perineal leakage ceased, and after two more treatments the wound had completely healed.

This case has convinced me of the importance of personally following up the after-care of patients until the wounds are healed, when possible. It is not safe to assume in all cases that the perineal wounds will take care of themselves if merely kept clean. While this is true of the majority, in a few, where there is a tendency for perineal leakage to persist, the passage of sounds, irrigation of the bladder and cauterization of the sinus will tend to prevent the formation of fistulæ. A little spur of granulation tissue at the point where the perineal wound joins the urethra may cause the deviation of a part of the urine through the perineum; unless this is corrected in time, the tract may become epithelialised and a persistent fistula ensue.

In no case as yet has a true stricture developed since operation (Case No. 42 was the nearest approach to this).

After-treatment is also indicated in cases of cystitis. The removal of prostatic obstruction will go far to cure a pre-existing cystitis, but in cases of long standing, especially those due to the colon bacillus, local treatment is advisable in addition. Four cases have suffered from cystitis since the operation. One (No. 12) is kept very comfortable by regular treatment in the Out-Patient Department. One (No. 19) is symptomatically well, but the urine still contains considerable pus with colon bacilli, in spite of treatment; there is probably a pyelitis present in this case. Two patients (No. 29 and No. 35) are troubled with considerable frequency of urination, undoubtedly due to cystitis; they have been without medical treatment. In every case in which the urine was clear and uninfected before operation, it has been a great satisfaction to find it equally so afterwards.

Data as to retention of sexual power are very incomplete. In 3 cases it is known to have been lost; in 2 there have been definite complaints on the subject. In 3 cases it has been fully retained.

### SUMMARY OF RESULTS.

A summary of the results obtained in these 24 cases of perineal prostatectomy shows that 2 patients died; in neither case was death directly due to the operation. All the others left the hospital in good condition with obstruction relieved. In 15 cases the end results have been excellent in every respect, all that could be expected or desired. In 2 other cases the result is marred only by the loss of sexual power. One patient has a persistent cystitis which is symptomatically controlled by regular treatment, otherwise well.

In four cases the results are not so satisfactory.

In one there is poor control of the bladder, so that the patient prefers to wear a urinal. In one other there is at times, under stress, lapses of control. Two patients have persistent perineal fistulæ; in one of these there is also some cystitis present.

*(To be continued.)*

## VACCINES IN PUERPERAL SEPSIS.

BY W. H. WATTERS, A.M., M.D.,

*Professor of Pathology, Boston University; Pathologist, Massachusetts, Homeopathic Hospital;*

AND

C. A. EATON, M.D.,

*Lecturer in Pathology, Boston University, and Assistant Pathologist, Massachusetts Homeopathic Hospital.*

DURING the past few years an immense amount of work has been performed, particularly in the English-speaking world, along the lines of vaccine therapy. Many highly trained specialists have used the method widely, with most encouraging results. Also many less skilled have employed it with less success. As a result, there is at the present time much confusion and uncertainty concerning the value of the new treatment, the scope of its usefulness and its limitations.

In furunculosis there is a practical unanimity of opinion that vaccine, properly administered, is by far the most efficient method of treatment. To a somewhat less extent the various forms of staphylococcus infection have been found to yield readily to these inoculations. Tuberculosis of various organs and tissues is quite generally admitted to be more readily eradicated when the use of tuberculin in minute doses is added to the other therapeutic measures employed.

To briefly summarize, in local affections of bacterial origin vaccines are at present rather widely recognized as very valuable adjuvants to the usual methods of treatment, and not infrequently render those other methods less important or even unnecessary. When general infections are considered, however, particularly those acute in nature, there is a much less unanimous opinion. Some claim that here vaccines are not only useless, but even harmful; while others, equally reliable, strongly uphold the opposite opinion. Certain it is that here the dosage must be much more carefully regulated by a more experienced observer than in the case of local lesions where even needlessly large doses seem to be often borne with impunity.

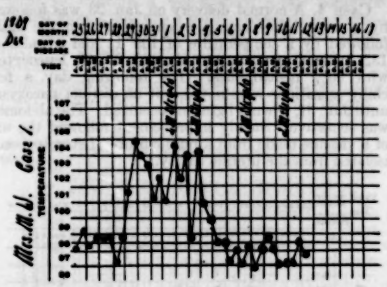
There are at present a number of acute infectious diseases, not infrequently characterized by a general dissemination of the bacteria throughout the body, in which the value of vaccine treatment is fairly debatable, even though from strictly theoretical considerations it should be useless. Chief among these may be mentioned pneumonia, erysipelas, typhoid and puerperal sepsis. The theoretical reasons why they should not be amenable to vaccines need not be considered in this paper as they are available to all without present unnecessary repetition. Thanks to Leary, of Boston, it has been clearly demonstrated that pneumococcus vaccine in pneumonia, when properly used, is without harm and probably gives rise to much benefit. The final results of his extensive clinical tests are looked for with much eagerness. Similarly, Ross, of Toronto, has demonstrated a fact frequently corroborated by others, that streptococcus vaccine is a valuable agent in reducing mortality, in checking the extension of and hastening convalescence in erysipelas. One of the writers of the present paper has elsewhere given his experience with typhoid vaccine where, with a considerable number of control cases, the mortality seemed to be diminished, the duration of the fever was less and the total residence in the hospital was shortened. During the past few months about twenty-five or thirty cases have been treated with vaccines, and thus far without any mortality, although upon admission some were critically sick.

It is, however, concerning puerperal sepsis that this article has primarily been written. On account of their connection with various institutions having maternity departments, as well as with a home for unfortunate girls, the writers have had a somewhat unusual opportunity of observing a quite large number of septic cases such as are now fortunately much less common than they have been in the past. Concerning the diagnosis of puerperal septicemia, a long discussion might be here interpolated. A difference of opinion would doubtless be encountered, some authorities dating its inception from the introduction of the bacteria into the uterine cavity, others placing it as the time of bacterial invasion of the blood stream and still others at intermediate periods. Such discussion is here omitted, although its value is distinctly recognized.

It will be perhaps sufficient to say that in the cases about to be cited, comparatively few were subjected to blood cultures, as on account of the usual acuteness and severity of the symptoms it was deemed wise to begin the treatment as soon as the microscope or the culture tube revealed the presence of streptococci in the uterus. It was, accordingly, upon this latter fact, in association with evidence in the blood of severe infection, and coupled with a distinct clinical picture of puerperal sepsis, that the diagnosis was usually made. In the great majority of the cases streptococci in pure culture were obtained from the uterine cavity; in a smaller number they were in association with staphylococci and in a very few instances staphylococci alone were found. It will be seen that in all fifty cases are reported. This includes all that have been treated, the good and the bad, the early and the late, the complete list being purposely given in order to show the failures as well as the successes, in this way giving a more accurate idea of the complete results.

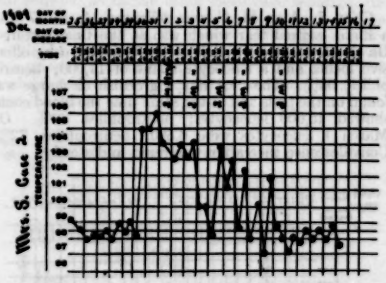
Among this series will be found a few that received ante-partum prophylactic injection on account of bacteriological findings or unusual opportunities for possible puerperal infection. These all recovered. It is of further interest that

certain others who likewise received prophylactic treatment showed pure cultures of streptococcus in the uterus post partum, but without any clinical symptoms of sepsis or other complication. This was never noted in other normal patients not so treated. Among the fifty cases reported, four died within twenty-four hours of the first treatment, being practically beyond any hope of recovery when vaccines were first requested. Three others were moribund when inoculations were begun. Here life was possibly prolonged two or three days. Apart from these, there are forty-three patients, two of whom died and forty-one recovered. Of the two that died, one was operated upon for suspected pus tube, which was not found, dying six days after; the other was subjected to blood transfusion, dying within a few hours.



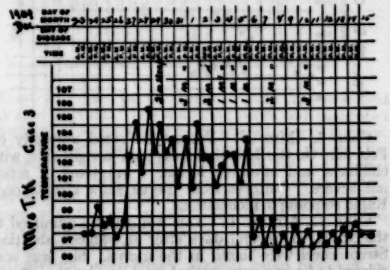
The method of using the vaccine was to administer a polyvalent preparation immediately after the diagnosis seemed definite, as determined by bacteriologic tests and to repeat as necessary until the autogenous preparation was ready, about twenty-four hours later. The vaccines were prepared by use of the minumum degree of moist heat, a method apparently followed by better results than when the earlier method was employed. Careful watch was made to ascertain any possible injurious effects or aggravation, but even in the worst cases none such could be demonstrated. On the contrary, a number of patients who seemed to be almost without hope of recovery made very happy convalescences. No claim is here made that the vaccines should replace other generally recognized methods. On the contrary, they should be used to assist all others that have proved to be of value. Unfortunately, such procedures of proven value are as yet only too few. In the series reported, a hot vaginal douche has been usually employed; very rarely, in only one or two cases an intrauterine douch. Curettage has not been performed in any instance. The bowels have been maintained in an active condition and remedies have been used when indicated. We have strongly advised leaving the patient as free from manipulation or local treatment as possible and believe that the results well bear out these instructions.

We prefer to draw no conclusions concerning the results of the treatment as a whole, as we realize that the ground is still debatable. We do, however, wish thus fully to detail our experiences, allowing the readers to decide from the results whether it is a method deserving of further study. Two facts may be given in conclusion: One is that no demonstrable harm has been often done to any person; the other, that patients have shown much improvement after the inoculations and have recovered when even the best clinicians have foretold a fatal termination.



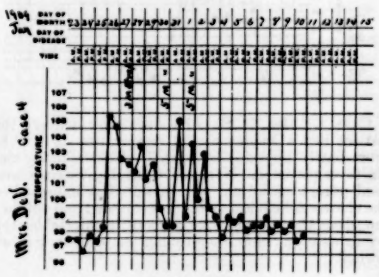
The following is a detailed description of the individual cases:

CASES TREATED.

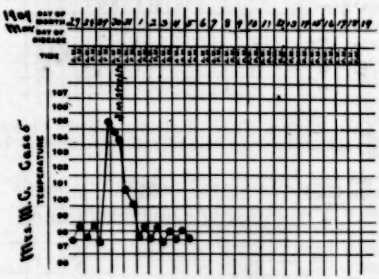


Case 1. Mrs. M. E. W. was delivered Dec. 26 after five days of ineffectual pain. Forceps were used. On the 29th she had a chill, followed by marked headache and backache. These continued to increase in severity until Jan. 2, then gradually subsided. Upon Dec. 31, streptococci in pure culture were found in the uterine cavity and an autogenous vaccine was made that was used the following day. This was followed by steady decline of all symptoms, including a marked inflammatory leucocytosis.

Case 2. Mrs. D. S. Five days after delivery this patient had a sudden rise of temperature to 105° F., immediately preceded by a chill. The following day the fever persisted. Upon the third day vaccines were used (streptococci) and were repeated as indicated on the chart. All clinical symptoms subsided and within a few days the patient was perfectly comfortable, this occurring even before the evening temperature reached normal.



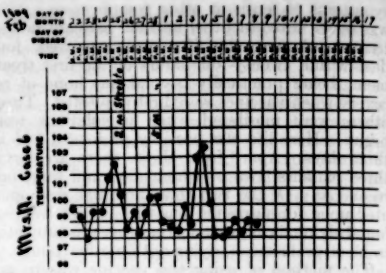
Case 3. Mrs. T. K. Following delivery by four days appeared a severe chill followed by rapid elevation



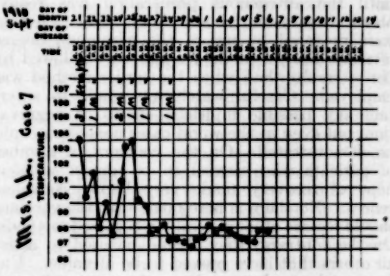
of temperature and the usual associated symptoms of sepsis, headache, backache, nausea and vomiting and

prostration. An autogenous vaccine was prepared. On the 29th, hysterectomy was seriously considered, hoping thereby to remove the original focus. Following the use of the vaccine, a steady amelioration of all symptoms became evident and this went on to an uninterrupted convalescence.

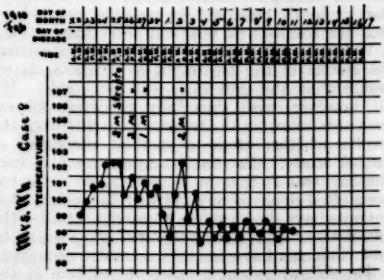
CASE 4. A normal delivery on Jan. 23 was followed by a severe chill lasting seven minutes on the 26th, followed by a temperature of 105° F. and a pulse of 132. Blood examination showed 24,000 leucocytes, with 90% neutrophiles. The following day a few chilly sensations were noted, but no distinct paroxysm until Jan. 31, when a light one occurred. The abdomen was sensative. Steady improvement followed the use of a vaccine made from a pure culture of streptococcus isolated from the uterine cavity.



CASE 5. Mrs. M. C. was delivered March 17 with a slight vaginal tear which was at the time repaired. On the 29th a violent chill occurred, followed by offensive lochia and a leucocyte count of 14,000; neutrophiles, 96%. The next day a greenish discharge was found on the pads and at the same time the blood count showed 15,000 leucocytes; neutrophiles, 89%. On March 1 leucocytes were 6,500; neutrophiles, 72%. Convalescence thereafter was rapid and steady.

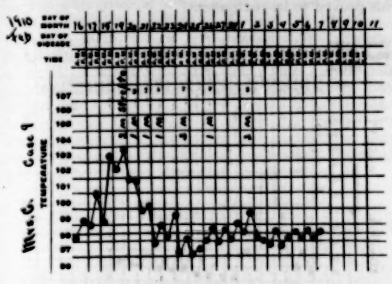


CASE 6. Mrs. N. Patient delivered normally on Feb. 22. On the 24th there was pain in right side, with chilliness and offensive lochia. Symptoms of sepsis not severe. Cultures from uterus show streptococci. Rapid response to inoculations.

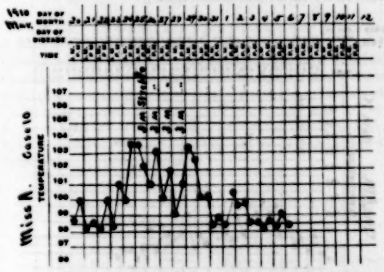


CASE 7. Mrs. L. L. This woman was admitted to the M. H. H. several days after an induced abortion. Streptococci were found in the uterus. She was considered to be in a very critical condition by the attending staff and was for two days on the "dangerous list." No surgical intervention was considered safe on account of the severity of the disease. Much to the surprise of the observers, a distinct improvement was

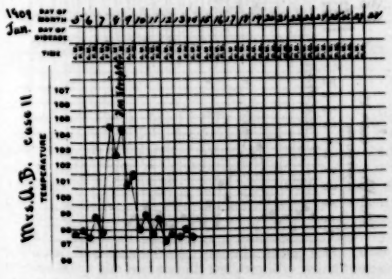
noted; at first slow, but within about two days much more rapid. Convalescence was complete.



CASE 8. Mrs. W. In this case a steady rise in temperature was noted as beginning within a few hours of delivery. Chilly sensations, but no distinct chill occurred. Following the use of vaccines, the steadily rising tide of fever was checked and with but a temporary exception on the 2d, was transformed into a steadily falling one.

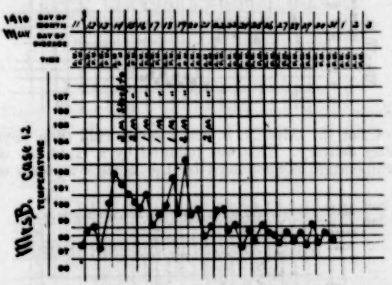


CASE 9. Mrs. C. Two days after delivery a febrile attack was ushered in by a distinct chill. This was accompanied by the usual symptoms characteristic of the average case of puerperal sepsis, including blood and bacteriologic study. The index of the progress of the disease is well given by the temperature chart, aggrava-

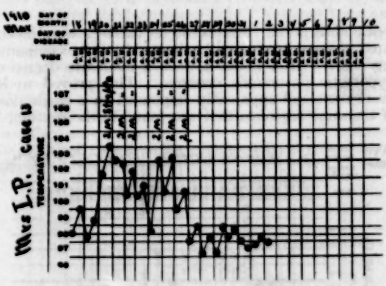


tion and amelioration occurring as the febrile condition indicates. The symptoms all steadily increased until the first inoculation, then as steadily subsided.

CASE 10. Miss A. This was the case of a young girl, unmarried. Upon the third day after a normal delivery the temperature began to rise and continued to do so for three days, with headache, nausea and chill. Immediately following the first inoculation, amelioration of symptoms appeared, together with decline of the fever. This was continuous and persistent.

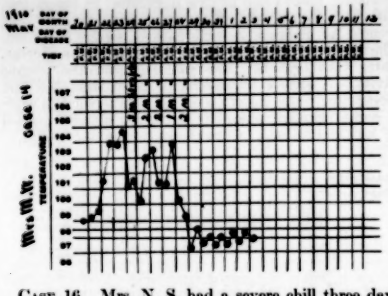


CASE 11. Mrs. E. B. Six days after a normal delivery there appeared a distinct chill followed by a marked elevation of temperature, headache and vesical

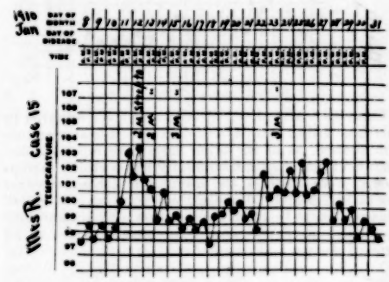


irritability. All subsided rapidly after inoculation. Streptococci in pure culture were obtained from the uterine cavity.

CASE 12. Mrs. B. This patient on the 13th and 14th was considered to be seriously ill by her attendants. The fever had been preceded by a chill and malaise, headache, nausea and general discomfort in association with a well-marked inflammatory leucocytosis. All seemed to indicate a well-marked septic condition. The first inoculation was a stock streptococcus vaccine. Later that organism was isolated from the uterine cavity. A steady improvement dated from the first inoculation. One injection on the 19th seemed to show a slight negative phase in the chart unaccompanied by any clinical one. Convalescence was uneventful.

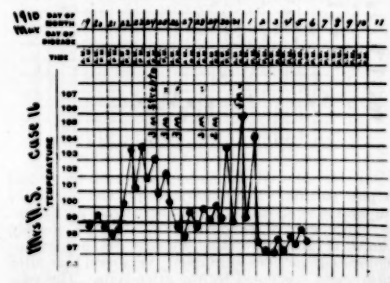


CASE 13. Mrs. J. P. A chill and fever occurred in this case within two days of delivery. Blood examination showed, as in the other cases here reported, distinct evidence of an inflammatory leucocytosis. Streptococci were found in the uterus. Following the first inoculation March 20 a slight amelioration was noted. This proved to be more marked from day to day until in about a week the temperature was normal and all signs of disease had disappeared.

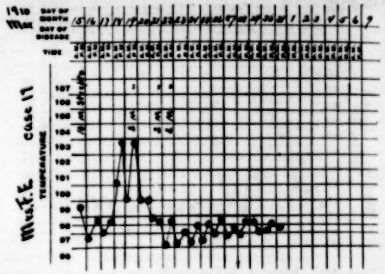


CASE 14. Mrs. M. W. had a severe chill the second day post partum. The following fever and associated symptoms of sepsis caused much alarm to her physicians. The entire clinical condition continued to steadily progress in an unfavorable manner till autogenous streptococcus vaccines were used. Very soon thereafter improvement was noted by the attendants. This continued with but slight and unimportant interruptions to a very favorable termination.

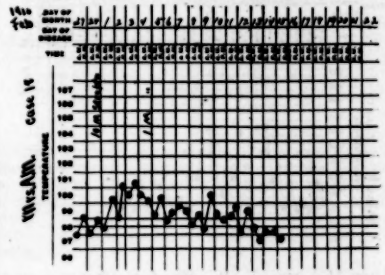
CASE 15. Mrs. R. A mild chill occurred three days post partum, after which came a rapid elevation of temperature. Streptococcus vaccine was made from a uterine culture. After inoculation all indications of sepsis apparently disappeared. In about ten days



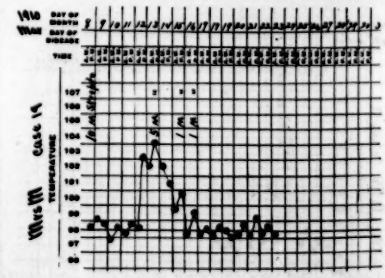
local symptoms of salpingitis were found. Operation revealed a small pus tube. Convalescence was uneventful.



CASE 16. Mrs. N. S. had a severe chill three days after delivery. This was followed by a rapid rise of temperature accompanied by the usual symptoms of

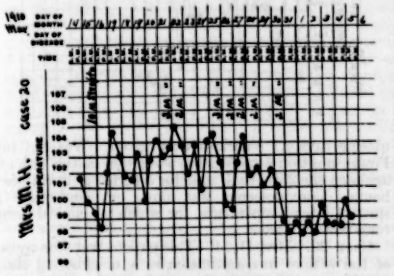


septic absorption. Streptococcus vaccines were inoculated, the result being well indicated by the accompanying chart. After about a week a moderate degree of hypostatic pneumonia occurred. This proved to be evanescent and apparently responded to a single dose of the same organism that was found in the sputum.

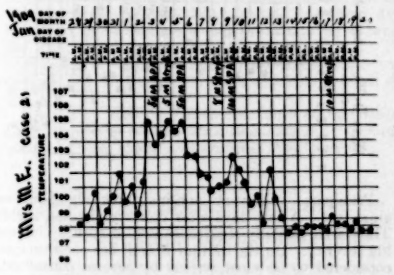


CASE 17. Mrs. F. E. A prophylactic injection of streptococcus was given on account of unusual exposure to infection. Two days after delivery a chill occurred, and after this fever, rapid pulse, malaise, headache and backache. Streptococci were recovered from the uterine cavity. Whether, however, this was a true case of sepsis or not, may not be definitely answered on account of the evanescent character of the disturbance, but at least it can surely be said that following the inoculation a very rapid subsidence of all symptoms was noted. This proved to be permanent.

CASE 18. Mrs. O. M. This patient had a very hard labor, including version and the use of instruments. Following this appeared mild indications of sepsis. Streptococci in pure culture were isolated from the uterine cavity. Whether the vaccines in any way influenced the condition cannot be positively stated. It did not progress to any greater severity and was followed by rapid convalescence.



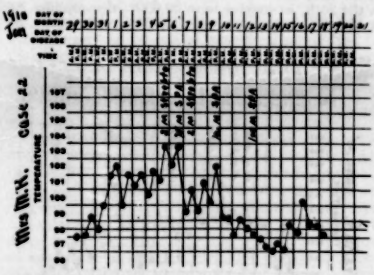
CASE 19. Mrs. M. This patient received a prophylactic injection of streptococci on account of exposure



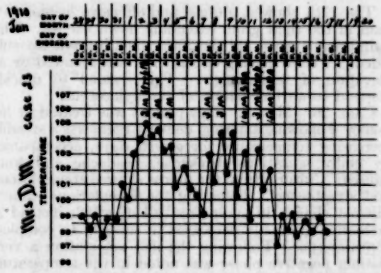
to possible infection. Four days post partum she had a chill with following fever, but not severe clinical symptoms of septic absorption. A stock streptococcus vaccine was administered as indicated. This was fol-

lowed by very rapid subsidence of the entire pathologic condition.

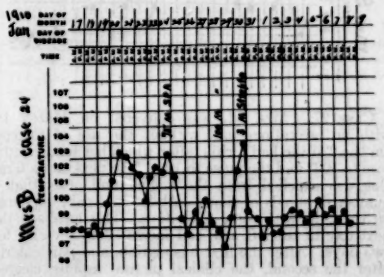
Case 20. Mrs. M. H. On account of an unusual amount of apparent exposure to possible infection, this patient was given a prophylactic injection of streptococcus just before delivery. In fact, at the time of injection, there was a not inconsiderable degree of fever. Immediately after the birth of the child a chill occurred, followed by high fever and rapid pulse. Cultures from the uterus showed streptococci alone. In spite of the temperature the patient did not seem to be very sick. On March 21, however, vaccines were first administered. From this time the patient began to improve clinically. Except for a slight hypostatic pneumonia, convalescence was uninterrupted.



Case 21. Mrs. M. E. This patient was delivered in a bath-room Jan. 28, with a slight perineal tear. On the 31st she had a bad headache and passed a number of clots per vaginam. On Feb. 2 the lochia was offensive and abdominal cramps were present. Leucocytes, 19,000; neutrophiles, 90%. Oct. 3 she was delirious and tried to get out of bed. Several chills followed by pain in right iliac region. Was better the next day and steadily improved thereafter.

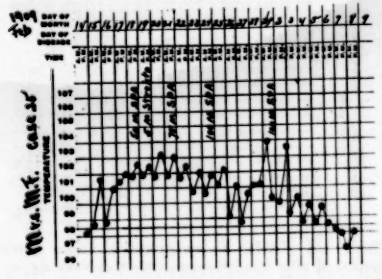


Case 22. Mrs. M. R. In this instance a rather gradual elevation of temperature was accompanied by mild symptoms of septic absorption. Cultures showed a mixed infection of streptococci and staphylococci. Vaccines of the former variety were used without apparent benefit, but with staphylococcus appeared distinct clinical improvement after each inoculation.

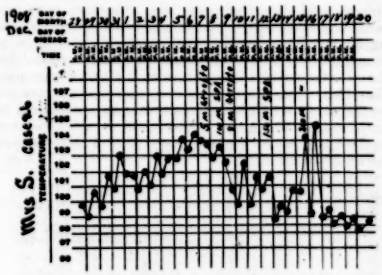


Case 23. Mrs. D. M. A primipara with history of previous bad leucorrhea. About three days after a normal labor she had a chill, with rapidly rising temperature and rapid pulse. The chill was repeated several times during the following three days. Cultures showed streptococci and staphylococci. Autogenous streptococcus vaccines were given and were followed by excellent clinical results for nearly a week, when some of the symptoms reappeared in a more mild form.

These, not yielding to streptococcus, were rapidly eradicated after staphylococcus vaccines were given.

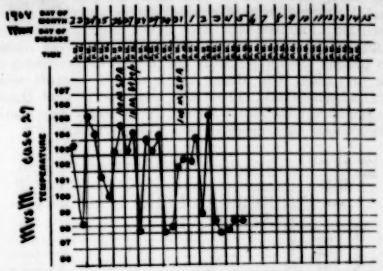


Case 24. Mrs. B. suffered from a severe chill three days after the birth of a child. Cultures taken at that time showed staphylococcus only. Vaccines were prepared and administered as indicated on the accompanying chart. This was followed by rapid subsidence of all symptoms. A second culture made a few days later showed streptococci in addition to the other organism. Therefore, when a second chill appeared, accompanied by the various febrile concomitants, an inoculation of streptococcus was given. The result is well indicated on the chart, which is also a close index of the course of the other symptoms.



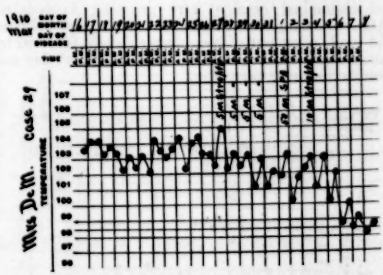
Case 25. Mrs. M. F. On Feb. 15 a normal delivery occurred with a slight vaginal tear that was immediately repaired.

On the 18th, leucocytes were 41,000; neutrophiles, 93%.
On the 20th, leucocytes were 50,000; neutrophiles, 85%.
On the 22d, leucocytes were 55,000; neutrophiles, 92%.
On the 25th, leucocytes were 39,000; neutrophiles, 86%.
On March 2, leucocytes were 36,000; neutrophiles, 84%.



The 17th showed profuse and offensive lochia, with pain in the right groin extending down the leg. This pain became worse till the 20th, when it gradually subsided. A chilly feeling on the 27th was followed by an elevation of temperature. This seemed to quickly respond to an inoculation of staphylococcus.

CASE 26. Mrs. S. This patient was treated at her home. Following a normal delivery there was a steadily increasing temperature for eleven days, accompanied by chilly sensations, backache, headache and some nausea. Cultures from the uterus showed staphylococci and streptococci. Following the inoculations came a distinct change in symptoms, all of which instead of increasing gradually decreased in severity to complete convalescence. Following the last inoculation a very distinct negative phase was noted in the temperature chart but unaccompanied by other clinical evidence of aggravation.



CASE 27. Mrs. M. was delivered on March 18, with no lacerations and without the use of forceps. On the 22d she had a chill, after which her temperature rose to 103° and the pulse to 108. The next day a large clot was expelled from the vagina and after that a number of shreds of tissue. Abdominal pain appeared on the 24th with some distention. This localized the next day in the left side and increased in severity for two days. After the first inoculation, and particularly after the second, the clinical picture rapidly cleared and the patient went on to a steady convalescence.

CASE 28. Mrs. E. I. On Nov. 13 a normal delivery was accompanied by a mild tear of the perineum that was immediately repaired. Membranes were ruptured by the physician's finger. On the 17th, marked abdominal soreness with chilliness appeared, accompanied by elevation of temperature and pulse. Leucocytes, 33,000; neutrophiles, 85%. Patient considered to be critically ill, with headache, lassitude and some stupor. Streptococci and staphylococci were found in the

uterine cavity. Vaccines were given. Was put into Fowler position with Murphy irrigation on the 19th and again on the 25th, each time for a period of twenty-four hours. Convalescence was slow, but continuous in spite of later temperature, for which no clinical symptoms were apparent.

CASE 29. Mrs. D. M. This patient was seen by one of the writers in consultation in a neighboring state. At this time the patient was examined, cultures were taken and the first inoculation administered. Later treatment was given by the attending physician who was in daily communication with the laboratory.

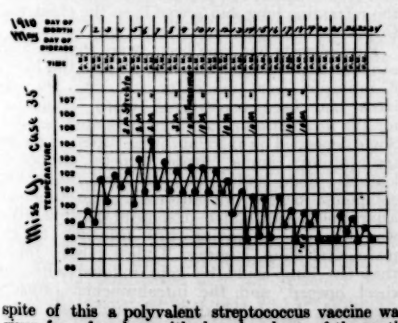
Primipara. Delivery non-instrumental, slight vaginal tear. A few days after delivery she had a chill. These were of daily recurrence and of steadily increasing severity. On the 27th of March her condition was considered to be most serious by several consultants. After cultures were taken autogenous vaccines were prepared and administered, but in the interim a polyvalent streptococcus preparation was used. The chills disappeared within three days, all the various symptoms steadily cleared up and complete convalescence occurred in a comparatively short time.

CASE 30. Mrs. H. H. Normal delivery, Feb. 21.

Feb. 23. Leucocytes, 18,000; neutrophiles, 76%.
Feb. 24. Leucocytes, 30,000; neutrophiles, 92%.

On the 22d there was a chill, followed the next day by headache and abdominal pains, increasing in intensity. The abdomen was somewhat distended and very sensitive. The lochia was offensive. On the 25th

abdominal hysterectomy was performed, at which time a diffuse peritonitis was found. Murphy irrigation and Fowler position was used, together with vaccines. Recovery was uneventful.

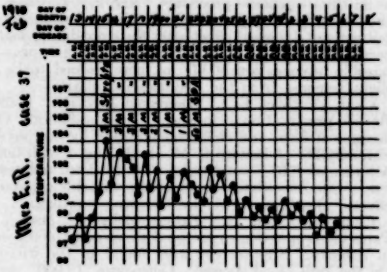


Case 31. Mrs. M. M. Confinement, May 10, without complications. Somewhat vacillating temperature after a few days, steadily becoming worse, with symptoms of peritonitis. On May 20 admitted to surgical service, M. H. H., and received vaccines. On May 29 abdominal incision was made, allowing escape of a considerable amount of pus. Wound closed and drained. Convalescence uninterrupted.

Case 32. Patient delivered at home March 9, with slight laceration. All went well for about nine days, when elevation of temperature and chills appeared. On the 22d she was admitted to the M. H. H. with temperature of 101.2 and pulse 130, following a chill. Under an anesthesia no condition was found to warrant radical operation, and after a uterine douche she was returned to her ward. Not showing much improvement, vaccines were requested and given. Clinical gain was soon apparent, which proved to be permanent in regard to the uterine condition. A somewhat vacillating temperature persisted, however, on account of which the patient was kept for some time in the hospital, but which was later found to be due to pulmonary tuberculosis.

Case 33. Miss E. S. An illegitimate pregnancy, in which infection occurred after instrumental intervention. The temperature chart is a good index of the rise and fall of the various allied symptoms, nausea, vomiting, chills, rapid pulse headache, etc. Leucocytes, 40,000; neutrophiles, 97%. A distinct amelioration of the very numerous and apparently serious symptoms was apparent upon the day following the first inoculation. This proved to be continuous to complete convalescence.

Case 34. Mrs. R. This patient showed a slowly but steadily rising temperature from the day following her delivery. The associated symptoms, while not very severe, were steadily increasing in intensity. A single injection upon the 4th did not apparently in any way check the progress, but a second one three days later was more successful and proved to have begun the incline back to normal of all the symptoms. The alternation of staphylococcus with streptococcus vaccine seemed to prove even more satisfactory than did the latter alone.



Case 35. Miss G. In this instance cultures taken from the uterus showed organisms similar to pneumococcus in size, shape and cultural characteristics. In

spite of this a polyvalent streptococcus vaccine was given for a few days with slow decadence of the septic symptoms. The decline was apparently much hastened, however, by the use of an autogenous preparation of the apparent pneumococcus.

Case 36. Miss A. J. The exact clinical condition here cannot be stated with certainty. Clinically, the case was said to be one of puerperal septicemia by all the attending physicians. An earlier febrile attack subsided spontaneously; the second one was accompanied by a chill and more severe symptoms than the first, but also subsided rapidly after the administration of vaccines.

Case 37. Mrs. E. R. About three days after delivery the temperature began to rise steadily. At this time cultures from the uterus showed streptococcus alone and in abundance. Following inoculation the septicemic symptoms steadily decreased in severity. Intra-uterine douches were at first given, three times daily, following which appeared symptoms of abdominal inflammation, distention, etc. The distention increased in severity but was apparently due, largely at least, to absence of peristalsis. Operation on Feb. 24, about two weeks after delivery, showed about a teaspoonful of pus near the Fallopian tube, well walled-off. Convalescence thereafter was very rapid.

Case 38. Mrs. G. W. Three days after childbirth this woman began daily chills, followed by high temperature. Autogenous vaccines were used and were followed by distinct clinical benefit. Local symptoms of peritonitis appeared, for which operation was performed. A very little pus, less than a teaspoonful, was found walled off in the pelvis. Vaccines were continued daily with rapid subsidence of all clinical symptoms. The temperature was less amenable, however, it vacillating as indicated without corresponding subjective or objective indications.

Case 39. Mrs. A. W. S. A uterine culture two weeks after delivery showed streptococci and staphylococci. Patient very neurotic and with marked anemia. Had several severe chills. Vaccines were used and were followed by complete recovery.

Case 40. Mrs. E. R. In this instance the temperature went up gradually during two days, associated with a rapid pulse, headache and backache. An autogenous streptococcus vaccine was administered once only. Owing to a change of service no repetition of the inoculation was made. She seemed to be doing well for about a week, when the fever and associated symptoms returned. On the 14th of April, not being satisfied with her progress, she left the hospital in which she was, against the advice of her physicians, and has since been lost trace of.

Case 41. Mrs. A. M. Five days after delivery a sudden rise in temperature was accompanied by severe headache, nausea and vomiting and offensive lochia. A single inoculation of streptococcus seemed to give

some slight amelioration. Blood transfusion was decided upon. Death occurred a few hours after the operation.

CASE 42. Mrs. A. G. A chill occurred the second day post partum. The febrile and septic symptoms continued to get worse for five days thereafter. When the patient was delirious and supposed to be hopeless, vaccines were requested. The first inoculation was followed by some amelioration of symptoms. Operation had already been decided upon and was performed on the 15th. Following this all symptoms steadily increased in severity and despite autogenous vaccines death occurred on the 22d.

CASE 43. Mrs. P. This patient was seen in her home, where she was considered to be beyond hope of recovery by a skilled consultant. Cultures showed streptococcus. Vaccines were given at intervals of three days and were followed by a slow but steady recovery.

CASE 44. Mrs. H. K. was delivered May 14, a breech presentation necessitating the use of forceps. Three days later chills and fever began and continued. Was admitted at the M. H. H. May 20 with temperature of 105° and pulse above 120. Curettage was performed as an almost hopeless procedure. Vaccines were begun the following evening and were continued for four days but without apparent effect after the second day, death occurring on the 30th. The only result here was a possible prolongation of life as there seemed to be a slight response from the first two inoculations.

CASE 45. Mrs. E. L. Delivered July 21 at home. Breech presentation — forceps. Child stillborn. On account of fever and chills was curetted by her physician July 28. Admitted to M. H. H. Aug. 2 with temperature of 100° F., and pulse 136, delirious and restless. One inoculation was given without apparent effect. Death occurred the following morning.

CASE 46. Mrs. D. Patient delivered Dec. 21. Pains in lower abdomen on the 25th, steadily increasing in severity. Streptococci were found in the uterus. On the 28th blood showed: Leucocytes, 12,000; neutrophiles, 97%. She was practically moribund when the first inoculation was given. At first there was a distinct amelioration of symptoms, but this proved to be merely temporary, death occurring in about three days.

CASE 47. Mrs. B. A Russian who could not speak English. Admitted to the M. H. H. on Jan. 17. No history obtainable. On admission was moribund and showed a large, tender uterus, from the cavity of which were washed shreds of necrotic tissue. Not benefited by any method of treatment. Death occurred within a few hours of the first inoculation.

CASE 48. Mrs. A. G. This woman had been sick with the disease for five weeks prior to her admission into the hospital. She was practically moribund when admitted. Vaccines seemed to render some increased resistance and to give rise to slight temporary amelioration. Death occurred ten days later.

CASE 49. Mrs. B. A criminal abortion was performed a few days prior to admission into the M. H. H., March 30. She was found to have general peritonitis; also a uterus much enlarged and boggy. Uterine irrigation was attempted, but without result. On April 1 a single inoculation was given a few hours prior to death, but withcut apparent effect.

CASE 50. Mrs. J. G. This woman had high forceps delivery March 31. Admitted to M. H. H. April 3 in a semi-moribund state, when, after examination, it was decided that nothing could be done. Vomiting was almost continuous and the patient was evidently in much pain. Blood on the 5th showed: Leucocytes, 14,000; neutrophiles, 95%. Death occurred the same day, no effect of the inoculation being apparent.

## INTRATHORACIC INSUFFLATION ANESTHESIA: APPARATUS AND CASES.*

BY ALBERT EHRENFRIED, M.D.,

*Surgeon, Mount Sinai Hospital; Surgeon, Boston Consumptives' Hospital; Assistant in Anatomy, Harvard Medical School.*

SURGERY of the thorax is to-day passing through the same phase in its development that characterized abdominal surgery of thirty or forty years ago. Until recently the thoracic cavity was, to the surgeon, unexplored territory. Intervention was restricted to the use of the needle for exploratory purposes and for aspirating the pleural and pericardial sacs, to thoracostomy and rib resection for drainage of empyemata, and to occasional thoracoplasties. In rare instances adventurous souls had overstepped these limits, but without assurance. Within the past few years, however, a small group of pioneers have blazed a trail into this unknown land.

In abdominal surgery the main problem which confronted the experimenter was the providing against sepsis. Our technic has now encompassed that, and we face the strange difficulties of thoracic surgery with greater confidence. The first major problem, the control of the pressure within the lungs during operation, has already been satisfactorily solved, and it is of the methods of preventing collapse of the lung that I wish to speak.

The danger of pneumothorax after perforation of the parietal pleura has always stood as the greatest obstacle to the advancement of intrathoracic surgery. In so great awe has it been held that men like Bardeleben, Roser and Bilroth advised strongly against taking any risk of damaging the pleura in removing tumors of the chest wall. Krause and Tuffier originated the method of detaching the pleura and conducting exploration extrapleurally. Bazy made a small incision in the pleura and immediately plugged it with his exploring finger. Sencert tried to meet the danger by admitting the air gradually through a small puncture. Delorme advised the formation of adhesions between visceral and parietal pleura by the injection of a chemical irritant some time previous to operation. Pean and Roux incised the pleura, seized immediately the retreating lung and sewed it to the chest wall to prevent complete atelectasis; and so on.

Physiologists had long been aware that animals could be kept alive by blowing air into the lungs, if provision were made for its exit. On this basis had been constructed many appliances for the insufflation of air in asphyxiated persons. Some depended on intralaryngeal tubes; some on tracheotomy canulæ, made of metal, rubber or leather. Some had a simple bellows, others had compound bellows for alternately injecting and aspirating the air, which, in some of the apparatus, was warmed. Applying this principle to experimental lung surgery, Tuffier (1897) found that the lung could be kept inflated with the chest opened, and the intrabronchial pressure regulated, by insufflation through an intra-

* Read before a clinical meeting of the staff of the Mount Sinai Hospital, March 15, 1911.

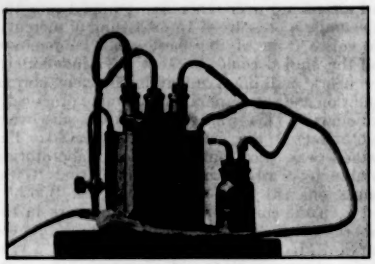
laryngeal tube. Quénu accomplished the same results with a helmet or box, containing air under pressure, into which the animal's head was placed. Then Kuhn and Lotsch devised the double tube, which allowed for the back-flow of the insufflated air. Soon after, Volhard, Hirsch, Sollman and Robinson demonstrated that oxygenation of the blood could be maintained without inflation of the lungs by supplying a constant stream of oxygen directly at the bifurcation of the bronchi.

Matas, of New Orleans, was one of the first to apply the principle of insufflation to human surgery. With Bloom, he modified the Fell-O'Dwyer apparatus for intermittent intralaryngeal insufflation by adding a pressure manometer, air filter and provisions for supplying chloroform vapor or oxygen to the air. This apparatus was successfully applied by Parham in a case of sarcoma of the chest wall (1898). About the same time Doyen devised an apparatus, differing mainly in that it had a double-acting pump. This form of artificial respiration, useful, indeed, in an emergency, has not been found practicable for continued anesthesia with the thorax open.

The first important step in the advancement of human lung surgery was the introduction of the negative pressure chamber of Sauerbruch. He discarded the idea of inflating the lung by positive pressure within in favor of maintaining a negative pressure without. His cabinet was a room, — to which he added later a lock chamber for entrance and exit, — within which the surgeon and his assistants worked upon the patient, whose head was outside. The air within the chamber was maintained at a negative pressure of about 5 mm. of mercury by means of an electric pump. The patient was isolated against the negative pressure, except for his thorax, by means of a rubber collar about his neck, where his head was thrust through the window, and a rubber bag tied about the waist and enclosing the lower half of the body, connecting with the outside air. Communication with those without was by telephone.

From the first operation upon a human being in Sauerbruch's cabinet (performed by Mikulicz in 1904) dates the new era in thoracic surgery. The principle was adopted without reserve, cabinets were built in several institutions and operations were performed which a few years before had been deemed impossible, such operations as resection of the lung for tumors and bronchiectasis, exploration of the lung and mediastina, resection of the esophagus for carcinoma.

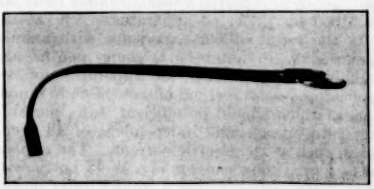
Under the stimulus of this new interest, means were sought to render the procedure more simple and thus more widely applicable, for the apparatus of Sauerbruch was both costly and cumbersome. Brauer found in his experiments that the original method of maintaining distention of the lung by means of positive pressure was less complicated and equally efficient. He accomplished this by placing the anesthetist and the patient's head within a cabinet, into which air was pumped under pressure, the operation being performed in the open room. Later the apparatus was further simplified into a box or helmet containing the head of the patient and the hands of the anethetist, and now positive pressure is usually applied by means of a mask which sets down over the patient's face.



At first there was some hesitancy about accepting the positive pressure method from suspicion that it might have some deleterious effect upon the lung tissue, but Dreyer and Spannaus showed by their experimental investigations that physiologically there was no difference between positive and negative pressure in their effects. Willy Meyer, of New York, and Robinson, of Boston, have combined the advantages of the two methods in so-called "differential" cabinets adaptable for work under either positive or negative pressure. Otherwise, the positive pressure method is now generally favored.

Two years ago, Meltzer and Auer, working in the Rockefeller Institute, found that if a tube about two thirds the diameter of the trachea was passed nearly to the bifurcation of the bronchi, and air passed over ether was pumped into this tube under a pressure of 15 to 20 mm. of mercury, the entire front of the chest could be removed and the animal could be kept alive indefinitely, the heart and lungs maintaining their normal condition and the diaphragm remaining practically stationary. This was a momentous discovery and attracted the attention it deserved. The method was tried out in various laboratories, notably by Carrel, who announced that it was simple, efficient and safe. Dr. W. M. Boothby and I, in the course of experimental work in the Laboratory for Physiological Research at the Harvard Medical School, took it up about a year ago and were so favorably impressed with its advantages as to simplicity and safety over the cone method of anesthesia that we have adopted it as a routine in all animal operations, with a distinct lowering of mortality.

The adaptability of this technic to the human being was at once apparent. Elsberg, of New York, soon had an apparatus ready which was fitted for this use, and within a few months he anesthetized the first case by this method, a patient of Dr. Lilienthal's, with lung abscess. Last month he reported a total of thirty cases and described his perfected apparatus.



As the result of our experience with animals (about sixty in number) I, some months ago, attempted to construct an apparatus for the application of this method of anesthesia to human beings, which should be efficient, safe, portable, simple to operate and independent of all accessories, such as the electric current. The apparatus as I use it now consists of a Wolff bottle with three necks, sitting within a copper water jacket, and a foot bellows. By means of cocks on the outside of the jacket, the stream of air from the bellows can be carried through the hot water, over the top of the ether (contained in the Wolff bottle), or through the ether when a particularly strong vapor is desired. Air and ether vapor may be mixed in any proportion. Connected with the delivery end of the apparatus is a safety valve

and pressure regulator consisting of a bottle of mercury into which a tube is plunged. The depth of the tube in the mercury, which is adjustable, represents the maximum of pressure which is allowed within the apparatus; if for any reason, such as a spasm of the glottis, the pressure should rise, the valve "blows off" automatically and danger from interstitial emphysema is avoided. In our early experience we employed a dial manometer registering in millimeters of mercury, to record the pressure, but we have found that the pressure bottle answers as well for all practical purposes. The apparatus is provided with a device to prevent droplets of condensed ether being carried over into the larynx. The air or mixture is supplied at a practically constant temperature of about ten degrees above room temperature; if the operation is to last over half or three quarters of an hour, the contents of the water jacket should be replaced. The air supplied may be filtered and moistened.

Apparatus for intratracheal insufflation anesthesia.

For an intratracheal tube we use a French lisle catheter, 22 to 24 F., moistened in hot water to render it pliable, a new and sterile one for each case. Soft rubber tubes have the advantage of standing sterilization by boiling better, but they are less easy to introduce. The chief difficulty with this method of anesthesia so far has been the introduction of the tube. We now use a simple

Introducer, for the introduction of the tube into the larynx.

introducer, a laryngeal forceps with sleeves attached for grasping the tube near its extremity, similar in principle to the introducer of Doyen. After considerable pains to produce the proper curve, — working on frozen sections and cadavers, — we have made an instrument which can be guided into the larynx in a matter of seconds, with the mouth gag in place and the left forefinger on the epiglottis, without the necessity of using a head mirror or electric illumination, or changing the patient on the table to and from the Rose position, as is necessary with the direct laryngoscope.

I have tried this apparatus now four times on human beings, as follows:

CASE I. Feb. 21. Patient of Dr. W. M. Boothby. Interscapulothoracic amputation. Ether, Dr. H. B. Loder. I introduced the tube on a stylet, properly curved. After some minutes it became evident that tube was in esophagus, and tube was removed, and no attempt made to reintroduce it. Recovery without complication.

CASE II. Feb. 28, Boston Consumptives' Hospital. Tuberculous synovitis forearm, necrosis skull. Ether, Dr. H. B. Loder. Patient given preliminary ether with difficulty, choking up with mucus to the point of cyanosis. Tube introduced readily with electrically illuminated Chevalier Jackson direct laryngoscope. Patient immediately became quiet, color improved, mucus disappeared and an easy anesthesia of one hour twenty minutes was maintained on 5 oz. of ether. The apparatus demonstrated how lightly anesthetized the patient could be kept and how effectively and quickly the grade of anesthesia could be controlled by means of the cocks. At the end of the operation ether vapor was blown out of the lungs by blowing in fresh air until no odor remained on the breath. Patient waked immediately to nearly full consciousness and suffered no nausea or vomiting. Patient doing well and no complication or untoward effect traceable to the etherization has developed.

CASE III. March 1, Boston Consumptives' Hospital. Massive empyema of long standing, cyanosis. Ether, Dr. Loder. The laryngoscope was in place when the lamp burned out. On account of extremely poor condition of patient, no further attempt made. Patient doing well.

CASE IV. A case of chronic empyema (Boston Consumptives' Hospital) several times previously operated, upon whom I did a radical and extensive thoracoplasty this morning (March 15). Ether, Dr. Boothby. The tube was readily introduced by means of the introducer already described. Condition was excellent throughout an etherization of one hour twenty-five minutes. Anesthesia quiet, without mucus and, although lying upon side of sound lung, no cyanosis. Gentle and rapid recovery, without nausea. Seven ounces of ether used.

The advantages of the method are apparent, even with so limited an experience. The air passages are kept dry of mucus, and inhalation of mucus, blood or vomitus is prevented by the return current of air about the tube. The anesthesia can be run at low pressure until occasion calls for higher, and after the occasion is passed it can again be lowered. The respiratory rate is an index to the amount of pressure. There are no bands of elastic constriction about neck or abdomen, and the anesthetist has free access to the patient's face and mouth without interfering with the pressure. No more ether is used than is needed within the lung; the ether vapor is washed out with air as soon as the anesthesia is over, and, therefore, recovery is rapid; the chance of excess ether or ether-laden mucus getting into the stomach is slight, accord-

ingly, recovery is gentle. The operator works under normal conditions, and his field is not limited by apparatus; the anesthetist may remain at some distance from the patient. There is no danger of the glottis falling back and closing the trachea. If the heart stops beating from any cause, the most efficient form of artificial respiration apparatus is immediately at hand. The apparatus is not complicated by machinery and requires no expert; with it there is no danger of overpressure.

This form of anesthesia has a wide scope of application outside of the field for which it was originally designed. In operations upon the face, mouth and neck it has obvious advantages. The operating field is unobstructed. Run at a low pressure, it will insure adequate ventilation of the lungs and obviate the possibility of aspiration of mucus or blood and thus lessen the frequency of secondary pneumonia following face and mouth operations in the elderly. Green reported a successful excision of epithelioma of the nose under its use, and Lilienthal has stated its advantages in cases of intestinal obstruction, obviating the danger of drowning in fecal vomitus, or of secondary pneumonia from the inhalation of septic matter. The apparatus is inexpensive and is adaptable for any form of vapor anesthesia, such as rectal ether, vapor-mask anesthesia, intra-oral vapor anesthesia and anesthesia through a tracheotomy opening (as for excision of the larynx). Complete with foot-bellows, it packs readily into a small suit case, and can be easily carried.

The apparatus as it stands represents a total expense of about twenty-five dollars. For about the same sum, one can add the inessential luxuries of an electric motor (one-eighth horse-power), rheostat and blower with a regulating by-pass to carry off the excess of air, to replace the foot-bellows, as well as some electric device for maintaining heat, — either an incandescent bulb within the water tank or a heating coil about the delivery tube. These are, however, unnecessary; they constitute an added complication and are advisable only where the apparatus is to be permanently installed, or where one is sure of having at his disposal the proper current.

## THE EXTIRPATION OF THE TONSIL BY ENUCLEATION: PARTLY INSTRUMENTAL, PARTLY BY THE USE OF THE FINGER.

BY L. M. FREEDMAN, M.D.,

*Surgeon to the Department of the Ear, Nose and Throat, Mount Sinai Hospital, Boston, Mass.*

Historically, the method described herein is an old one. Too far back in the history of medicine has this operation been done for any one of the present day to claim originality in using it. The method is new only in its modifications, one of which is here briefly considered.

It is of interest to note that, so far as we know, the finger method was employed before any other tonsil operation. In the year A.D. 10, Celsus described a method of enucleation thus:

"Tonsils . . . should be loosened by working the finger around them and then torn out; but when this is not practicable, they should be seized by a hook and excised with a scalpel."

From the time of Celsus to that of the most recent, literature makes no mention of the finger method. However, other forms of completing the tonsillectomy with forceps and bistoury are given from the earliest times. The use of the cold wire snare to complete the enucleation is not mentioned until late in the nineteenth century; but, what might, in a measure, be compared to it, is the employment, in early times, of the ligature before cutting off the freed tonsil. Ambrose Paré, 1509, mentions the ligature of hypertrophied portions of the tonsil, but does not advise excision. His pupil Guillemeau speaks of excision of portions after ligature but does not advocate the removal of the tonsil entire. After the ligature method had fallen into comparative disuse for nearly a century, it reappeared, after 1740, under the influence of Wiseman, whose method was to ligature portions and then to excise. Since then it has become one of the recognized surgical procedures.

Fig. 1.

The purpose of this paper is to demonstrate the superiority over others of the finger method when combined with some of the present-day means for accomplishing tonsillectomy. The advantages in the use of this method have been found to be: the easy and quick separation of the tonsil from its bed; the ability to palpate with the finger behind the tonsil an abnormally large or malplaced artery; and the minimized chances of hemorrhage. The only disadvantage which this method may have is the somewhat slower healing observed in cases where the traumatism of blunt finger dissection between the tonsil and the soft palate structures has been more severe than usual. But with experience and care this condition may be forestalled.

The armamentarium consists of a mouth gag, one tonsil tenaculum, a tongue depressor, two Leland knives, — one right, one left, — one double-

edged knife of the Smithwick type, and a tonsil snare of the Farlow type.

In children, general anesthesia, usually ether, is used; in adults, local anesthesia is preferred.

FIG. 2.

For the latter, submucous injections into the anterior pillar, the posterior pillar and into the supratonsillar fossa of a .5% cocaine or novocaine, or 1% of quinine and urea hydrochlorate, are used.

FIG. 3.

There are five steps in this operation:

1. Separation of the anterior pillar. (Fig. 1.)
2. Incision into the supratonsillar fossa. (Fig. 2.)
3. Finger dissection of the tonsil anteriorly and posteriorly. (Fig. 3.)
4. Snare engaged over the tonsil and tightened. (Fig. 4.)
5. Handle of the snare turned and tonsil gradually excised. (Fig. 5.)

In detail, this operation is performed as follows: With the gag in place, and the tongue depressed, the right Leland knife is introduced between the anterior pillar and the tonsil of the right side, as in Fig. 1. With a slightly sawing motion downward the lower half or three quarters of the anterior pillar is separated from the tonsil. The tonsil is then seized with the tenaculum forceps and drawn inward and forward toward the median line, thus making tense the mucous membrane, which is continuous from the soft palate over the tonsil. The double-edged knife is then introduced at the superior margin of the tonsil, between the tonsil and the soft palate, severing the mucous membrane and entering the supratonsillar fossa. (Fig. 2.) This incision is continued forward between the tonsil and the anterior pillar and backward between the tonsil and the posterior pillar.

FIG. 4.

The forefinger is then introduced in the supratonsillar fossa (Fig. 3), between the tonsillar capsule and the tonsillar sinus. With the finger used as a lever downward, forward and then backward, the tonsil with its capsule intact is gently separated from the tonsillar sinus until all but its very base is free from attachment and hangs loosely in the foreward part of the mouth, though still firmly held in the grasp of the tenaculum forceps. In fact, in some cases it is possible, after this manner, to separate entirely the tonsil;

but, in order to be sure of leaving intact the posterior pillar attachment in the tongue, it is wiser, ordinarily, to leave the rest of the tonsil for final separation by the slow crushing and cutting force of the snare.

The loop of the snare is then placed over the tenaculum forceps until it passes the tonsil and engages firmly the very root of the tonsil (Fig. 4); it is then tightened and the ratchet fixed. The head is inclined forward and the tenaculum forceps and snare handles held together. The ring handle of the snare is slowly turned until the tonsil is entirely cut off. Occasionally, if the snare has not been properly adjusted over the very base of the tonsil, a small piece of tonsil is observed hanging loosely between the pillars. This is so free that the punch forceps will easily remove it at once.

Fig. 5.

The employment of this method over all others in our clinic has characteristically reduced the bleeding and has quickened the time of operation and has produced less injury to the pillars — a frequent source of hemorrhage in other methods.

Objection has been urged that the finger more than a metallic instrument is a source of possible infection; this is a possibility, but one that is hardly worth consideration. Surgical asepsis and antisepsis of the hands are in these days sufficient to insure perfect safety in this regard. Further, as an instrument of intelligence and power, the finger has no equal. (Grateful acknowledgments are hereby made to Dr. S. H. Rubin for the drawings accompanying this article.)

---

The late Dr. Samuel Alexander bequeathed all his surgical instruments and pathologic and anatomic preparations to Cornell University Medical Department. — *Jour. Am. Med. Asso.*

## Clinical Department.

### LATE CÆSAREAN SECTION — REPORT OF A CASE.

BY STEPHEN RUSHMORE, M.D.,

*Gynecologist to the Carney Hospital; Instructor in Clinical Gynecology, Tufts College Medical School.*

Cæsarean section, under the most favorable circumstances, has given such gratifying results that it is not surprising that the operation should be resorted to in some of the less favorable conditions. When the baby is in good condition, and the mother, just before or at the beginning of labor, normal except for some bony deformity which makes delivery in the natural manner impossible, the indications are clear. In cases of placenta previa, eclampsia, prolonged labor with ruptured membranes, there is not yet unanimity of opinion as to the advisability of abdominal operation; and, if operation is performed, whether trans- or extra-peritoneal, whether with or without hysterectomy. If infection of the mother is probable, the question is still further complicated.

Some surgeons refuse to operate if the patient has been subjected to vaginal examination; others, unless they are sure of the observance of strict aseptic precautions during the examination. Some operate even in the presence of known infection. The limitations of the operation can be determined only by a careful study of many cases under varying conditions. However, to refuse operation, when mother and child are in good condition, because the mother *may* be infected, is to take a position which, I think, will not be sustained by experience, and which is not based on humanitarian grounds.

The case reported is of interest because of the gratifying result after fifteen hours of labor, three with membranes ruptured, when delivery with forceps on the floating head had been attempted in vain. While the only definite conclusion that can be drawn from one favorable case is that operation was the right thing at this particular time, the case is thought to be of sufficient interest to merit recording. Credit is due to the physician who first saw the case, for his careful asepsis during examination and manipulation of the attempted vaginal delivery.

Mrs. M. K. Gyn. No. 675. Age, twenty-seven.

*Past history.* — Patient has always had some trouble with right hip; thought it was rheumatism. Following a fall eleven years ago, began to be worse; considerable lameness and pain in right leg. Patient was never confined to bed on account of hip. Twenty years ago, patient had an attack of measles after considerable trouble with throat.

*Menstrual history.* — Onset, sixteen; irregular and painful.

*Married history.* — Has never been pregnant before.

*Present illness.* — On July 3, 1910, 9 A.M., patient began to have labor pains. About 8 P.M. operation had been decided upon, the patient was etherized and forceps delivery attempted. Soon after midnight, the patient was admitted to the Carney Hospital.

*Examination.* — Patient a dwarf, with some deformity of the lower spine and apparently of the pelvis also. Temperature, 100; pulse, 120. In pretty good general condition. Child rather small, position occiput-right-posterior; head not engaged. Fetal heart 144, regular, good quality. External conjugate, 16 cm.

*Vaginal examination.* — Cervix, 5 cm. in diameter, easily dilatable further. Head could not be made to enter pelvis. Fontanelles not felt as caput thick and patient rather sensitive. Promontory of sacrum could not be felt. The pelvic arch fairly wide; outlet of pelvis apparently large enough if head could have entered pelvis.

*Operation.* — The abdomen was shaved and painted with tincture of iodine. Under ether, it was again treated with the iodine just before making the incision. Median abdominal incision from the umbilicus to 8 cm. above the symphysis. The uterus was delivered and packed around with numerous dry towels. Uterine incision from top of fundus downward on anterior wall about 10 cm. long. Considerable meconium on opening amnion. Male child easily delivered, slight contraction ring around neck of fetus. Placenta and membranes removed and cavity packed with dry gauze. Uterine incision closed in two layers, No. II chromic catgut — interrupted — for the muscle, not including peritoneum or endometrium; and a continuous chromic catgut suture to approximate the peritoneum and superficial part of the muscle. Before tying the last sutures the dry gauze was removed from the uterine cavity and a large gauze drain, sopping with Wright's solution (sodium chloride and sodium citrate), was introduced, passing from the uterus to the vagina. Closure of abdomen in three layers; tension sutures of silkworm gut.

Ergotole, MXX, given hypodermically at time of skin incision and on removing placenta. The uterus reacted well, no excessive bleeding. Pulse, 154, on leaving the table, but quality good.

The baby was slightly etherized, but breathed well from the first and soon cried. The body was thin, the head relatively large. It showed the marks of the forceps, good application. On the third day weighed 6 lb. The baby was put to the breast for a few days, then bottle fed entirely.

*Convalescence.* — The patient never looked very sick, in spite of considerable abdominal distention. Pulse about 100. Temperature irregular, up to 102°, reaching normal on the fourteenth day. The uterine drain removed in thirty hours. There was some induration of the lower part of the incision, from which about 2 drams of pus evacuated on the tenth day. Patient out of bed on the twentieth day, and went home on the twenty-sixth day following operation.

*Examination on discharge.* — Small granulating area in lower part of abdominal incision. No abdominal tenderness. Some increased resistance above symphysis.

*Vaginal examination.* — The promontory of the sacrum could not be felt. The right side of the pelvis easily felt to the pelvic brim and back almost to the sacro-iliac synchondrosis, thus presenting marked flattening in the oblique diameter. The left brim of the pelvis felt for very short distance. Fundus rising half way to the umbilicus.

NOTE: February, 1911. — Baby very well, normal in every way. Mother in good general health. Some pain in right hip and leg (under treatment in the orthopedic department for tuberculosis of hip). Menstruation reappeared Nov. 3, 1910. Very severe pain all over abdomen, chiefly in mid-line low down. On Dec. 8, flow less and pain less. On Jan. 11, flow normal, pain only in region of umbilicus — not severe.

## Medical Progress.

### PROGRESS IN DERMATOLOGY.

BY HARVEY P. TOWLE, M.D., BOSTON.

### THE TREATMENT OF SYPHILIS BY THE DIOXY-DIAMIDO-ARSENOBENZOL "606" OF EHRLICH-HATA.

ALTHOUGH Dr. Pellier[1] has limited this article entirely to a review of the German work with "606," he has covered the field so completely and marshaled his data so systematically that the result is one of the clearest and most comprehensive expositions of the subject which has yet appeared. Below is given a somewhat free translation of much of Dr. Pellier's review. Here and there certain unessentials have been omitted, and occasionally, for brevity's sake, the full text has been condensed.

Dr. Pellier has divided his review into three parts. In Chapter 1 he presents the facts relating to the history of the evolution of "606," its chemistry and the experimental work. In Chapter 2 is given a summary of the various technics, and in Chapter 3 the method from the clinical point of view.

#### CHAPTER 1 — HISTORICAL, CHEMICAL AND EXPERIMENTAL STUDY.

In the opening paragraph it is stated that "arsenical medication is no novelty in syphilography. In its various forms arsenic has been used many times with advantage, but without any one of its preparations having proved itself a therapeutic agent worthy of replacing definitively and in every case mercury and its compounds. To-day the question is raised once more apropos of Ehrlich's ideas and his preparation '606.'"

The good results obtained by the use of atoxyl[2] in sleeping sickness led by analogy to the use of the drug in syphilis. Hailed by Spiethoff and others as a specific, atoxyl gave such poor results in the hands of Curschmann, Tomaczewski, Zeissel and Mertchewski, etc., that the latter denied its supposed superiority to mercury. Moreover, intoxications and grave ocular accidents were observed so frequently after its administration as to lead to its gradual abandonment.

Having treated dourine by the combined use of atoxyl and the sublimate of mercury, Uhlenhuth conceived the idea of using a chemical combination of atoxyl and mercury in the treatment of syphilis. In fowl spirillosis, and in the experimental syphilis of rabbits, his results were brilliant. In man, Lesser, Mikley, Blascho and Boetke obtained good curative effects from this atoxylate of mercury without any serious mishaps. Boetke, however, was obliged to revert to the use of mercury in two cases out of fifteen. Hoffmann did not consider the drug superior to mercury, and preferred his own method, the use of insoluble preparations of mercury and

[1] Dr. Pellier: Ann. de Dermat. et de Syph., November, 1910.
[2] Atoxyl is the sodium salt of paramidophenylarsenic acid and its arsenic is pentavalent (Fig. 1).

arsenic either in the form of arsenious acid or Fowler's solution. Bergrath also considered it inferior to mercury, at least in the tolerated dose. In man, a dose proportionate to that which gave to Uhlenhuth and Mulzer the brilliant results observed in the rabbit would necessitate the injection at one time of 0.32 gm. of mercury and 0.24 gm. of arsenic.

Ehrlich, who had given especial study to atoxyl, thought that it could be replaced with advantage by arsacetin, the sodic salt of the acid acetylaminophenylarsenic, that is, by an acetylized atoxyl. This product was less toxic than atoxyl and was very active against the spirilli of recurrent fever and at the same time effective against trypanosomes. Ocular accidents, however, did occur. Neisser abandoned its employment, while Borcher proved that it had almost constantly a deleterious action upon the kidneys.

The next product, arsenophenylglycin or spirarsyl, numbered 418 in Ehrlich's series, marked a distinct advance along the way of this new therapeutic method. Whereas in the preceding compounds the arsenic was present in penta-atomic form, in spirarsyl it occurred in its tri-atomic state.[3] Ehrlich believes that arsenic will give results in the organism only when used in this tri-atomic form and that, therefore, it is along this line that atoxyl and its derivatives must be modified.[4]

Wendelstadt and Schilling having demonstrated that spirarsyl was extraordinarily active against animal trypanosomiasis, Alt was asked to undertake the investigation of its action upon man. In 100 cases of old syphilis, Alt found the Wassermann reaction to have disappeared in 16 and to have been diminished in 27, while some improvement was noted in cases of beginning paralysis. Neisser, after having had good success in the treatment of syphilis in monkeys, reported good results in severe cases of human syphilis, in tabes, in leucoplasia and in cases in which mercury had failed.

Alt very quickly abandoned the treatment by gradual increase, "by steps," in favor of the use of a single concentrated attack, the injection of 0.8 to 1 gm. of arsenophenylglycin in two consecutive days. He had noted that the prolonged administration of repeated small doses produced organic lesions in the test animals, while, provided the animal survived the intoxication, a single large dose left these same organs intact. This again confirmed Ehrlich's idea of a single massive dose. Alt's observations as to the harmful effects of repeated small doses upon the organs were confirmed by Klein, Eckard, Ulrich and Scherschmidt and by Raven.

This interesting therapeutic discovery leads by natural transitions to a consideration of some of the principles of Ehrlich's chemotherapy.

The protoplasm of the parasites possesses groupings, called chemo-receptors. When the medicament is more strongly attracted by the receptors of the parasites than by those of the living organs, the remedy is said to be parasitotropic; in the contrary case, organotropic. Ehrlich has demonstrated that the arsenicals are rendered efficacious, in the case of the trypanosomes, by an arseno-receptor in the parasites which is able to fasten them to the arsenic in its tri-atomic form[5] and that a purely chemical diminution of this affinity suffices to produce types of arsenic-resistant trypanosomes.

Ehrlich believes that it is of great importance to the vitality of the cells of the higher organism that they should only rarely, if possible only once, come in contact with a dose smaller than the dose immediately harmful. The best remedy will be that which kills all the parasites of the infected organism in a single dose; that will be the "therapia sterilisans magna." The first experimental study will be to determine the smallest fatal dose or, better, the largest non-fatal dose, for the test animals, — the dosis tolerata. Then after infection of the animal with a fixed dose of parasitic material and study of the process thus evoked, the dose which will cause the disappearance of the parasite must be found, — dosis curativa. The best therapeutic agent will be that in which the fraction $\frac{\text{dosis curativa}}{\text{dosis tolerata}}$ is the smallest.

Ehrlich found the best experimental material in spirillosis of rats, mice and fowls and experimental syphilis of rabbits, because in these infections the parasites in the blood could be counted with the microscope. The infected blood was diluted with non-infected blood to such degree that it contained, in a given amount, a determined number of parasites and when injected intraperitoneally produced an infection of moderate intensity. After having been tested in the test tube, the remedy was given either by mouth or hypodermically. In the latter case, the action was estimated by the motility of the parasites as seen upon the illuminated dark field. In animals, and always in spirillosis of fowls, the parasitic effect was measured by counting the number of spirilli in the blood by aid of the dark-field illumination. The absence of parasites under the microscope, however, was not an absolute proof of their disappearance from the organism, for an emulsion of the organs of an animal apparently cured sometimes successfully inoculated other subjects. The control of the cure by the possibility of a reinfection should also not ignore the fact that the previous evolution of the disease has created a certain degree of immunity in the animal.

In the course of his experiments Ehrlich met with what he called the "effectus contrarius." For example, in the test tube, certain dyes of the thiaziene series exhibited a certain effect upon the spirilli of recurrent fever in that, in a mixture of infected blood and a dilute solution of the dye-stuff, the spirilli became motionless and an injection of the mixture would infect either not at

[3] Having, therefore, the double molecule, as in "606" (Fig. 5).

[4] Compare the penta-atomic form in Figs. 1 and 4 with the tri-atomic form in Figs. 5 and 6.

[5] Figs. 5 and 6.

all or only feebly. In the body of the infected animal, however, the injection of a concentration of methylene blue, for example, five hundred times as great as that which was parasiticidal in the test tube for a few days diminished the number of spirilli but then apparently stimulated their increase.

The dyes of the benzidin group, although possessed of a certain power against trypanosomes, gave uncertain results in the test tubes and showed a parasiticidal effect in the injected animal only when the infection was much attenuated.

Atoxyl, which yielded some success in man to Glaubermann and Iverson, gave no results in mice when injected subcutaneously. Its preventive administration by mouth appears to have retarded development without influencing the intensity of the relapses. Arsacetin was found to be a little more active. Arsenophenylglycin was not preferable.

The series of the substances which had a real sterilizing action upon experimental spirillosis begins with arsenophenol (Fig. 3). Injected in large doses (1-2000) it gives permanent results, but a single larger dose (2-1500) is not efficacious. In the same way tetrachlorarsenophenol and tetrabromarsenophenol must be given in multiple doses in order to effect a cure.

The acid dichlorphenolarsenic, although possessed of a more favorable relationship of the dosis curativa to the dosis tolerata, was discarded because mice showed lasting nervous complications.

Hata's researches have been particularly concerned with an arsenophenol, the dioxydiamidoarsenobenzol (No. 592) (Fig. 5) and its chlorhydric salt (No. 606) (Fig. 6). Dioxydiamidoarsenobenzol is a clear yellow powder which oxydizes so easily that it must be kept in sealed tubes. It is not soluble in water without the addition of soda. Its dichlorhydrate is slowly but completely dissolved in water, giving an acid solution which is resorbed by the organism with difficulty. The addition of soda lye produces first a monochlorhydrate, a neutral salt, which is immediately precipitated. The addition of soda in excess redissolves this, forming an alkaline salt.

To obtain the sodic salt of dioxydiamidoarsenobenzol, Hata prefers to use "606" rather than "592," for, while the result of the two methods is identical as regards efficiency and toxic properties, less alkali is required to dissolve the fresh neutral precipitate from "606" than the dry powder of "592."

The following letter is from Mr. E. F. Billings, of the Billings Clapp Company, manufacturing chemists, in reply to a request for a simple explanation of the chemical manipulations by which Ehrlich transformed a toxic substance into one comparatively non-toxic:

"EHRLICH'S '606' AS SEEN THROUGH A PRACTICAL CHEMIST'S SPECTACLES.

"You say that your chemistry is a little rusty as the professors used to teach it, and you got all tied up in a knot trying to trace the chemistry of '606'?

"It is really very simple if you get away from technicalities and reduce it to some basis which will enable you to compare it with something familiar.

"At college they did this by comparing molecules with the bricks which an architect uses to build a building with. I never liked that comparison, and it seems to me more true to nature if we consider the molecule a machine, and the chemist the inventor, who takes different mechanical contrivances of well-known action and puts them together in a machine which as a whole will perform some very beautiful, and possibly very delicate, operation.

"To understand how Ehrlich goes to work, I think that this is the way you want to look at it. Consider the molecule as the *machine* which he is trying to *invent*, and the parts which must be put together as the atoms of our well-known series of atomic substances. Another reason why a molecule can be considered more clearly as a machine than as a brick is that the properties of the molecule are due more to its motion than to the actual matter of which it is composed; that is, if you build a building of red bricks, you have a red building, but if you build a molecule of white phenolphthalein and white carbonate of soda, you get a pink building. What you really do is, you take a molecule which you call phenolphthalein, and work it in with another device which you call carbonate of soda, and the product of your machine is that pink solution. The molecules which you work with are traveling with enormous rapidity and at a speed such that they collide at a rate of perhaps five billion collisions a minute, and these are the cogs in the several cog wheels of the machine.

"Kelvin illustrates the *size* of the molecules by saying, if a globe the size of a football is magnified to the size of the earth, and each molecule magnified in the same proportion, each molecule would be between the size of a round bird shot and an orange.

"Just as we may liken the molecule of a compound to a machine built to work, so we may consider the atoms, which form the molecule, as the wheels and cams and other parts of the machine, for an atom is always absolutely the same as every other atom of the same kind, just as a wheel of twenty cogs will always turn one twentieth as fast as a pin revolving so that it strikes one cog of the wheel at every revolution. It makes no difference whether you tip the wheel upside down or inside out, it is always just the same, and that is the way with any particular kind of atom. The spectroscope shows that an atom of hydrogen in a star so far away that the ray of light which we catch in our spectroscope now had started on its journey from the star long before America was discovered, by its refraction shows that it is exactly the same as any other atom of hydrogen that we find in our chemical work.

"With our thought centered on this imaginative conception of the atoms of matter as machine parts, and the molecules as machines, consisting of different combinations of those atomic parts, we can, in a rough way as it were, watch Ehrlich in his machine shop trying one contrivance on the machine he is building, and then another and another.

"The main part and starting point is the benzol ring, as we call it, which is the pedestal of all our aniline colors and drugs (Fig. 2).

"The discovery of the medical properties of atoxyl was the first step which brought to mind the possibilities of such a class of products. Keeping our imaginary machine picture, we see in atoxyl the benzol ring base of our machine with an arsenic combination at the top (Fig. 1). Arsenic was not new in this department of therapeutics, but arsenic in this kind of

a machine (the aniline base) was new and proved to have valuable properties, but it insisted on attacking the host as well as the parasite.

"To understand how Ehrlich went to work, look at the matter from the standpoint of the machinist again. How to make a machine along similar lines to atoxyl which would more perfectly perform the functions desired and at the same time would not have the trick of making trouble. The proper name of atoxyl by grace of chemical nomenclature is paramido-benzol-arsenate of sodium, which, being interpreted, means sodium salt of a compound consisting of the benzol ring with amid in the para position and arseniated (Fig. 1). That part of this machine which Ehrlich started to modify was the cog wheels, etc., of the amid group attached to the benzol ring.

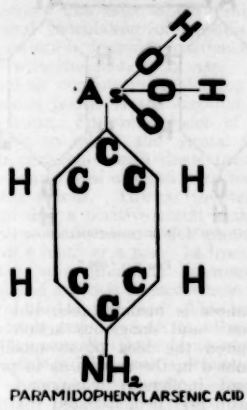


Fig. 1.

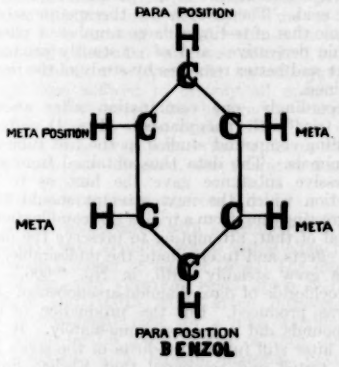

Fig. 2.

"What Ehrlich set out to do was to develop that property which we call selective affinity, which simply means that the chemical coming in contact with a lot of different things will show a property of selecting certain particular things in that mixture to attach itself to.

"For instance, methylene blue colors only nerve tissues, and neutral red colors only the cell granules.

"The machine which Ehrlich was trying to build was simply a machine which would have this selective affinity for the parasitic agents of infective disease, and leave the rest of the body alone, just as, for instance, methylene blue attacks the nerve tissues only.

"Ehrlich's method of developing of this machine, the reasoning which he followed and the imagination involved in the conception is one of the greatest achievements of mental process over material agents, and this is true whether the '606' turns out to be a specific or merely a product useful in certain combinations of disease. The medical properties of most chemicals have been discovered haphazard, but here is a man who dissects the tiny molecule to find out which of its wheels is responsible for the action he wants and which for the action he must eliminate, and by analogy and imaginative logic he determines the amid group to be the key to the action of the molecules. After a long tedious series of experiments, he finally secured approximately what chemical action he wanted in the preparation called '592' which goes by the graceful name of dioxydiamido-arsenobenzol.

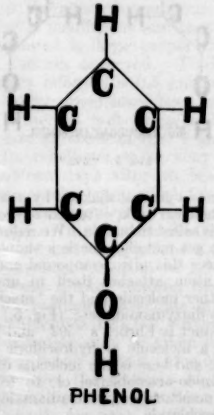
"But the machine did not yet operate successfully until another attachment was added; by sticking on the amid group hydrochloric acid, the '606' was then a fact instead of a figment of the imagination.

### *"Building the Machine.*

"To visualize the procedure here is benzol (Fig. 2)

"Oddly enough, by putting an atom of oxygen between one carbon and hydrogen atom, the volatile naphtha-like benzol is changed into our well-known carbolic acid. (Figs. 2 and 3.)

"The process of manufacture adopted by Ehrlich begins with this carbolic acid molecule, and by analogy with 'atoxyl' he tries putting a molecule of arsenic acid into the machine exactly opposite the oxygen of



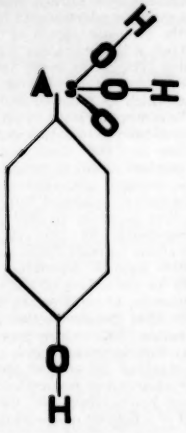


Fig. 3.

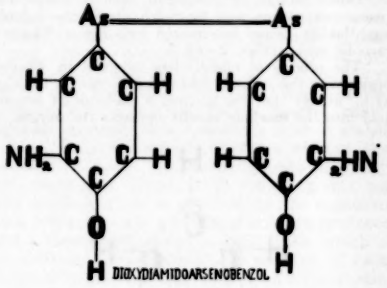
the carbolic and gets para-oxy-phenyl-arsenic acid. (Fig. 2, 3, 4.)

"This is treated with nitric acid in such a way that



the nitro group is attached to the 'machine' at what is called the meta position. (Fig. 2.)

"This product is meta-nitro-para-oxy, etc.

PARAOXYPHENYLARSENIC ACID

FIG. 4.

DIOXYDIAMIDOARSENOBENZOL

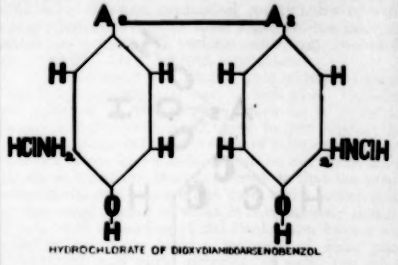


FIG. 5. "592."

"Now comes a general shakeup by a treatment very common in chemical work, — to take oxygen out of molecules, which is called reduction. We reduce the mineral zinc oxide to get metallic zinc is a simple illustration. Ehrlich reduces this nitro compound and in so doing the arsenic atom attaches itself to another arsenic atom of another molecule and the 'machine' doubles up, giving us dioxydiamido, etc. (Fig. 5.)

"This product is Ehrlich's '592' and the final step is to attach a molecule of hydrochloric acid to each amine group, and here is the molecule of '606' (Fig. 6), dioxydiamido-arsenobenzol or, to follow the full description nomenclature, metadiamidoparadiarsenodiphenylhydrochloride.

"This name is, you see, a description of the molecule which is the hydrochloride, of the amine group in the metaposition, of arsenic in the paraposition, of two phenol or carbolic acid molecules (compare Figs. 2 and 6)."

Ehrlich claims for Bertheim, Hata and himself absolute priority in the discovery of dioxydiamido-arsenobenzol. Its composition is not based upon a simple happy modification of atoxyl,* but is, on the contrary, the result of long synthetic work. That there is a relationship between the

HYDROCHLORATE OF DIOXYDIAMIDOARSENOBENZOL

FIG. 6. "606."

two substances is incontestable, but it is the "murderous" and dangerous action of atoxyl which inspired the idea of so modifying the elements joined in the arsenic as to produce an efficient and inoffensive compound. Ehrlich and Bertheim first demonstrated that the composition of atoxyl is quite different from that given out by Bechamp thirty years before and that it is a sodic salt of the para-aminophenylarsenic acid. Thenceforth the therapeutic scheme became that of testing a large number of phenylarsenic derivatives and of constantly producing better and better remedies by study of the results obtained.

Accordingly, one combination after another was tried with phenylarsenic (Fig. 4) and the resulting compound studied in the test tube and in animals. The data thus obtained from each successive substance gave the hint as to the direction which the next attempt should take. Progressing thus, from a trial of this combination to a trial of that, attempting to preserve the desirable effects and to eliminate the undesirable, the series grew steadily until, in No. "606," the hydrochloride of dioxydiamido-arsenobenzol (Fig. 6) was produced. But the production of new compounds did not cease immediately. It was only after still further products of the series had been tested and compared that Ehrlich finally returned to "606" and gave it his preference.

The final choice was based upon tests of the curative effects of the different compounds, the relationship of the curative to the tolerated dose, their toxic effects, solubility, etc.

No. "606" having finally proved its superiority in the laboratory and in the animal tests, Hata was given charge of its further investigation. In the spirillosis of fowls he established the relationship between the curative and the tolerated doses as follows: Atoxyl $\frac{C}{T}=\frac{1}{2}$; arsacetin =

* Compare Figs. 1, 5 and 6.

$\frac{1}{3.3}$; arsenophenylglycin = $\frac{1}{3.8}$; atoxylate of mercury = $\frac{1}{2.5}$; dioxydiamido-arsenobenzol = $\frac{1}{3}$; amido-phenolarsenoxide = $\frac{1}{3}$.

Two manifestations of syphilis in rabbits were studied: the syphilitic keratitis and the syphilitic scrotal lesion. The lesion which results from the experimental inoculation of syphilis upon the rabbit's scrotum possesses particularly striking analogies with the chancre in man.

The technic consists in implanting in a small subcutaneous pouch in the scrotum a piece of infected tissue. For transmission of the disease from rabbit to rabbit the scrotal inoculations are made preferably with tissue from a specific keratitis as it is less charged with bacteria than the scrotal lesions. Toward the tenth to the fourteenth day a positive result manifests itself by a small red infiltration which gradually attains the size of a lentil or a pea. In from four to six weeks the skin gradually necroses, becomes crusted and a lesion is formed whose borders are raised and hard as cartilage. This lesion usually persists from two to four months, sometimes longer. Occasionally there is no ulceration but only a nodule riddled with spirochete.

Hata preferred the scrotal lesion for therapeutic study because of its easy and constant accessibility.

In the treatment of syphilitic keratitis the minimum dose employed was 0.006 gm. per kilogram, given intravenously. Two or three weeks were necessary for the cornea to become completely clear, but cure was obtained in every case without a relapse. In scrotal syphilis a single dose sufficed to destroy all spirilli completely and at once; the chancre was completely healed in two or three weeks. The limit of the curative dose was found to be from 0.01 to 0.015 gm. per kilogram, the tolerated dose 0.1, so that $\frac{C}{T}$ was, therefore, from $\frac{1}{7}$ to $\frac{1}{10}$.

Neisser has treated with arsenobenzol a dozen monkeys with syphilis, whose initial chancre was cured in a longer or shorter time. The dose was 0.025 gm. per kilogram when given intramuscularly and 0.015 when given intravenously. (A proportionate dose for a man weighing 160 lb. would be 1.6 gm.) Three of these animals reinoculated with human material developed syphilis after a normal period of incubation. These three animals Neisser considered as having been cured. Three other animals injected and then reinoculated under the same conditions as the preceding developed after the same delay not typical primary lesions, but suspicious infiltrated and desquamating lesions which were probably syphilitic, as two controls developed undeniable syphilis.

Neisser also inoculated several monkeys twelve days after the injections and found the primary manifestations to be delayed ten to fifteen days longer than in the control animals.

Margulies found that the trypanosomes quickly became accustomed to "606" when the dose was augmented slowly and cautiously. They no longer disappeared even when the maximum dosis tolerata was reached; the parasites had become arsenic-resistant. With the spirilli this resistance to arsenic was attained only after a long series of passages; they survived double the dosis tolerata, although they apparently lost their initial virulence. The spirilli of recurrent fever showed no resistance to arsenic even after fifty-nine passages, as they disappeared when the dose was slightly increased. Such was also the case with the spirochete of syphilis. On the other hand, the rats were able, at the end of two or three weeks, to withstand double the fatal dose.

These therapeutic experiments are the more interesting for because of them one can explain the failures in "606" by an arsenic resistance.

In frambesia, Nichols, like Ossola and Truffi, practiced the scrotal inoculation of rabbits after the method used in syphilis. The scrotal lesion of frambesia differed from the lesion of syphilis only in degree. Contrary to the experience in monkeys, the scrotal inoculation of rabbits produced an energetic Wassermann reaction and innumerable spirochete were found. After verification of the lesion, the inoculated rabbits received 0.0045 gm. arsenobenzol either subcutaneously or intravenously, a dose twenty to twenty-five times smaller than the dosis tolerata. Within twenty-four hours the spirochete had disappeared and within two or three days the tumefaction was effaced.

### CHAPTER 2 — THE TECHNIC OF THE INJECTIONS.

In conformity with Alt's and Ehrlich's directions, most experimenters used a dose of 0.3 gm. To-day, it is the almost unanimous opinion that this quantity is insufficient and that to that fact can be attributed a large proportion of the relapses and failures observed. To-day the dose quite generally adopted is 0.5 gm., more or less. But much larger doses have been given without ill-effects. Fraenkel and Grouven have arrived by progression at doses of 0.9, 1 gm., and even 1.2 gm. In rebellious cases they have given 0.7 gm. fourteen days after an injection of 0.4 gm. and two weeks later, when the arsenic had apparently been completely eliminated, a dose of 0.8 to 1 gm. In this manner 47 men and 26 women received in two injections a total amount of "606" varying from 0.45 to 1.8 gm. and, in three injections, a total running from 1.6 up to 2.4 gm. Wechselmann also has given in three consecutive injections 0.25, 0.5, 0.5 gm. Although the second injection may be given in eight days, he considers it better to wait three or four weeks.

Ehrlich believes the question of dosage to be of the greatest importance and that it should be calculated afresh for each individual case. In subjects with disease of the nervous system whose hearts and nervous centers may react "in a disagreeable manner" he believes that the dose should not exceed 0.4. As, in such cases, the

number of spirochete is certainly minimal, small amounts of the medicament should suffice to accomplish their eventual destruction. But Ehrlich agrees with Neisser that this destruction should be attained in vigorous subjects by the first injection. The dose can be run up to 0.8 or even to 1 gm. without danger and may be increased by a method of combination such as Iverson uses.

Iverson, with the object of obtaining at the same time a rapid effect upon the spirochete and a continued action of the medicament, gives first an intravenous injection of 0.4 to 0.5 gm. and then at the end of forty-eight hours an intragluteal injection of 0.3 to 0.4 gm. This method by which the total dose can easily be augmented without violent reaction as high as 0.75 or 0.8 gm. was recommended by Ehrlich at the Königsberg Congress.

The two methods of injection, the intravenous and the intramuscular, have each their advantages without, however, either showing any particular superiority over the other.

With the exception of Fraenkel and Grouven's case (and this case has not yet been accepted by Ehrlich) the intravenous method does not appear to have produced any ill effects. Schreiber has given three hundred and twenty-five intravenous injections without accident. Although this method gives a little more rapid results, it is, nevertheless, more difficult of application. Since the first trials of the intramuscular injections, numerous modifications have been made in the method which have diminished its painfulness considerably. Many have used subcutaneous and intrascapular injections which are in no wise less painful but nevertheless allow the patient to continue at his work. At first it was universally believed that the patient should be kept in bed for several days, but little by little this belief has been modified.

Ehrlich stated in a recent circular (Oct. 25, 1910) that the subcutaneous injection of a neutral emulsion gives less permanent results than the other methods. The reason for this is the difficulty of obtaining an emulsion absolutely fine and regular, so that in consequence resorption is uneven, resulting in persistant infiltrations which tend to soften and necrose. The injection of a neutral emulsion came into favor because of the pain which follows the use of an acid or alkaline solution. Its temporary success is sufficiently explained by the resorption of small quantities of this very active preparation.

The painless and harmless intravenous injections seem to yield better results. Not only may the intravenous injection be repeated in two or three weeks, but, according to Ehrlich, it should be repeated if the curative effect of the previous dose has been insufficient. Indeed, injections have been repeated not only two and three times, but even four and five. While Alt and Schreiber have never exceeded 0.4 to 0.5 gm., Weintraub in some cases has reached doses of 0.7 to 0.8 gm.

Nothing has been published which shows that the mercurial treatment is contra-indicated by use of "606." Neisser, indeed, recommends it in particularly severe cases. In some cases, resistant to arsenobenzol, the mercurial treatment has been substituted or renewed without any inconveniences. Volk systematically employs a mixed method. It is to be noted, however, that Greven states that the mercurial treatment retards the elimination of the arsenic, while the iodide of potassium hastens it.

*Technic of Injections.*

We have seen that arsenobenzol may be used in three forms, in either acid or alkaline solution or in a neutral emulsion. The injection of the acid solution has been abandoned because, according to Alt, it is not devoid of toxicity, because even in small doses it has an unfavorable influence upon the heart, and because unless completely alkalinized the small elimination shows that but little of the substance gets into the circulation. Alt, therefore, has modified his technic as follows: 10 ccm. of sterilized water and the medicament are introduced into a glass cylinder of 100 ccm. capacity together with thirty glass pearls. [Schamberg makes the valid objection to the use of glass pearls that pieces of glass are liable to be chipped off.] When shaken energetically the substance is rapidly dissolved. Then there is added to each 0.10 of the substance, 0.5 of normal soda solution. When shaken for a half minute the solution becomes perfectly clear and if dissolution is not perfect it is because there is a slight excess or else a lack of soda. The total quantity may then be increased to 20 or 30 ccm. without injuring its clearness. A greater quantity renders the sensation of tension more painful, although less lasting.

Herxheimer shakes and grinds 1.5 gm. of arsenobenzol in 1 ccm. of a 5% soda solution. To the yellow mass resulting he adds, carefully, enough distilled water to obtain a fine suspension. The mixture is tested with tourmesol paper and neutralized with 2% acetic acid. The quantity is then increased to 10 ccm. with distilled water.

Schreiber, who employs the intravenous method, uses a glass cylinder of 250 ccm. capacity, which contains 10 to 20 ccm. of sterilized water. He adds 0.3 of the substance for women and 0.4 for men. When once dissolved, enough sterilized water or physiologic serum is added to bring the total amount up to 100 ccm. He then adds 0.7 ccm. of soda lye for each 0.1 gm. of the medicament. A precipitate forms which redissolves upon shaking, or if not, the addition of a few drops of soda will bring about the solution. The quantity is now increased to 200 ccm. by the addition of warm distilled water.

Wechselmann and Lange at first used Ehrlich's technic of a methyl alcohol solution of "606." This, however, they soon abandoned because of its painfulness and liability to produce untoward effects. The fear of toxic effects likewise caused them to give up the use of phenolphtalein. Lange then modified the technic, dissolving the "606" in a mortar with 1 or 2 ccm. of commercial soda

solution. Acetic acid was added drop by drop until a fine yellow deposit was produced. The precipitate was then recovered and mixed with 1 or 2 ccm. of distilled water. The whole was then neutralized as exactly as possible with 10% soda, or 1% acetic acid.

Bayet also uses this same technic.

Michaelis endeavored to get rid of the pain caused by injection of strongly alkaline solutions by using a neutral solution, but as the arsenobenzol is dissolved with difficulty under these conditions, one had to inject a medicament of which the greater part remained in suspension. While the simple neutralization of the aqueous solution by means of soda lye gives an irregular and clumpy precipitate, the neutralization by an acid of the solution obtained from an excess of soda yields, on the contrary, a liquid quite suitable for injection, having in suspension fine and regular elements. The clinical results being equally good, Michaelis developed the following technic: In a 50 ccm. cylinder there are placed from 0.3 to 0.6 gm. arsenobenzol and 16 ccm. of very warm sterilized water. The substance is stirred and broken up by means of a glass rod. When solution is obtained, from 3 to 5 ccm. of soda lye is added. It is then shaken and three drops of phenolphtalein in one half of 1% alcoholic solution is added. The mixture is then completely decolorized by acetic acid. The result is a fine suspension of a yellow color. Several drops of soda are then added until the red of the phenolphtalein barely reappears.

From the description of these technics we may share Blascho's opinion that all of these methods demand too great exactitude and too much asepsis to be intrusted to a practitioner or a pharmacist, and that for the present their use should be limited to institutions. Blascho, however, has remarked that, in spite of the necessity proclaimed by Ehrlich of the extemporaneous preparation for injection, the solution can be left for several hours without harm. It may be that aseptic solutions can be preserved indefinitely in sterilized tubes and be delivered to the practitioner in this form.

Kromeyer has used the following technic in over a hundred injections. A certain quantity of arsenobenzol, 3 gm. for example, is broken up very fine in a sterilized mortar with a very small amount of liquid paraffine. The mixture is then turned into a glass-stoppered vial and the amount of paraffine is carried to 30 ccm. in such fashion that each cubic centimeter shall contain 0.10 gm. of the medicament. The mixture must be shaken to get rid of the deposit, and needles of quite large caliber must be used.

Theoretically it is an objection to the use of such an emulsion that its absorption is relatively slow as compared with the solution ordinarily used. As a matter of fact, however, Kromeyer's clinical results do not differ from the others. Moreover, assimilation must be rapid since after the injection of 0.4 they have recovered in the urine, twelve hours later, 1.12 mgm. of arsenic, and in the next twelve hours, 12.7 mgm.

Volk has used an emulsion made with olive oil. Taege uses the following method: He first assures himself that the powdered "606" is quite movable in its tube, which proves that no air has entered. This is turned into a small test tube into which he pours two drops of glycerine per decigram and then a small quantity of warm water which has been held in readiness. The necessary material in this method is, therefore, most simple.

The method of Citron and Mulzer is even simpler than Kromeyer's. The solution is prepared in a syringe of 15 ccm. capacity. The powdered arsenobenzol is poured in and moistened with several drops of alcohol. Then distilled water is added up to the mark 5. The piston of the syringe is replaced and the syringe shaken. A clear golden-yellow solution is obtained. The piston is now once more removed. Forty drops of carbonate of calcium at ten to a hundred in suspension in artificial serum is added slowly while shaking constantly. The carbonate is designed to precipitate the base. The emulsion is then ready for immediate use. This method has numerous technical advantages and its clinical results are equal to those of the other methods. Its advantages are a unique recipient, easier asepsis, a perfectly neutral solution without the necessity of minute reactions, an injection nearly painless and the amount of vehicle reduced to a minimum (5 ccm. to 6½ ccm.).

(*To be continued.*)

## Book Review.

*Case Histories in Pediatrics.* A Collection of Histories of Actual Patients Selected to Illustrate the Diagnosis, Prognosis and Treatment of the Most Important Diseases of Infancy and Childhood. By John Lovett Morse, A.M., M.D. Boston: W. M. Leonard. 1911.

The purpose of this volume is stated in the descriptive sub-title, but a brief review is inadequate to detail its merits; it attracts as well as deserves study. The value and advantages of the case method of teaching in medicine have for several years been established. This book demonstrates that the method is not restricted to the class-room. The hundred judiciously selected cases which compose it form an epitome of pediatrics, and the discussion of each under diagnosis, prognosis and treatment is a refreshing and vital substitute for the theoretic chapters of the conventional textbook. To the reader, whether student or graduate physician, these cases not only serve as concrete examples of clinical types of disease, but afford invaluable and unconscious training in the best methods and habits of dealing with clinical facts as they present themselves in actual practice. From every point of view the volume should be of abundant service to members of the profession, and not least because it represents the author's ripened experience as a teacher and as a practitioner.

## INSPECTION OF TENEMENT HOUSE WORKROOMS.

A LAW of the Commonwealth of Massachusetts provides that "a family which desires to make, alter, repair or finish coats, vests, trousers or wearing apparel of any description in a room or apartment in a tenement or dwelling house shall first procure a license therefor from a state inspector of health, which shall be approved by the State Board of Health." A printed circular issued by the State Board of Health is left with every householder of a license. The circular reads as follows:

1. The apartments, stairs and hallways must be kept in a cleanly condition at all times.

2. The rooms must be well aired. The windows of the living rooms as well as of the sleeping rooms should be partly open at all times.

3. The sewing should be done in the room designated by the State Inspector of Health, and in no other room.

4. During the process of finishing, the garments should not be placed in any room that is used as a sleeping apartment.

5. Immediate notice should be sent to the State Inspector of Health in case of occurrence of a communicable disease in the family of the person holding the license, or in any family in the same building. Any case of skin disease in the family of the person holding the license should also be reported to the State Inspector of Health.

6. In case of removal, immediate notice must be sent to the State Inspector of Health.

7. The work on wearing apparel must be done on the premises designated on the license, and only by the members of the family of the person holding such license.

8. The number of occupants of the apartment should not exceed the number specified by the State Inspector of Health.

9. The license may be revoked on violation of any of the above regulations.

By close co-operation with the local health authorities the occurrence of every case of communicable disease known to the health officials is discovered; the premises are visited at once and if necessary the license is revoked.

There are, in Suffolk County, about 1,600 licensed tenement workrooms. Since Dr. Linenthal's appointment as State Inspector of Health he has inspected some 7,000 homes and issued about 4,000 licenses. Over 200 cases of communicable disease have been investigated and the necessary steps taken to guard the public health. While some workrooms are in homes where the sanitary conditions are beyond reproach, many are located in the congested tenement district and require constant inspection.

In the congested district a comparison of the licensed flats with those that prevail in other flats of the same building discloses a very striking difference in the sanitary conditions in these two classes of homes.

Briefly stated, the methods of inspection and licensing of tenement house workrooms, under the supervision of the State Board of Health, within the meaning of the law have resulted in (*a*) the maintenance of higher sanitary standards in such rooms; (*b*) a greater protection to those persons who are licensed to work on articles of wearing apparel, and to the public, from communicable diseases; and (*c*) the development of higher standards of hygienic living for persons in other flats and buildings where no licenses are required. Thus it is clear that the problem of inspecting tenement house workrooms is preeminently and exclusively one of public health.

## CLAUDE MARTIN AND AUTOLITHOTRITY.

AN item in the February number of the *Indian Medical Gazette* quotes from the *Asiatic Journal* for 1816 two interesting accounts of the manner in which the celebrated Franco-Indian surgeon, Claude Martin, operated upon himself for stone in the bladder. During his later years, Martin suffered severely from vesical calculus, and, being unwilling to undergo lithotomy, devised an instrument by means of which he performed lithotrity on himself. This instrument, according to Dr. Scott's account in the *Asiatic Journal*, consisted of a file, made from a properly tempered knitting-needle, fixed to the end of a piece of whalebone. This Martin passed into his bladder through a canula till it touched the stone, and then moved the file backwards and forwards till the stone was reduced to powder, which was

subsequently passed with the urine. The calculus recurred, and Martin is said to have repeated the procedure many times. "So accurately from habit could the Colonel [Martin] judge of every circumstance, that he could tell when any part of the surface of the stone became more elevated than the rest, and could remove that part with the greatest nicety."

The second account of this surgical episode, published in the *Asiatic Journal*, describes in addition the repeated recurrence of the calculus, from which Martin died in 1800. Apparently Dr. Martin must have been a man not only of great mechanical ingenuity, but of remarkable fortitude and perseverance as well, who interpreted and applied literally the scriptural injunction, "Physician, heal thyself." His experience illustrates further the nicety of manipulative technic that may be acquired by practice even in difficult maneuvres with crude instruments and under painful circumstances.

## THE DIP-TANK DECISION.

A YEAR ago this spring, the Boston Board of Health issued an ordinance forbidding the sale of so-called "loose milk" from dip-tanks, and requiring that all milk offered for sale in this city must be in separate receptacles properly sealed. This regulation, intended to safeguard the purity of milk supplied to consumers purchasing in small quantities, went into effect on May 1, 1910. It was bitterly opposed by milk dealers on the ground that it greatly increased the expenses of their business and diminished the amount of their sales. Under its provisions, a certain dealer was fined $10 before the Municipal Court for non-compliance with its requirements. From this fine he appealed, and the case went before the Supreme Court. On April 4 of last week, the Court handed down its decision that in making this regulation the Board of Health exceeded its statutory authority and that the ordinance and all prosecutions under it are, therefore, void. In rendering this decision, the chief justice says in part as follows:

"We do not consider the question whether this regulation goes beyond the constitutional power of the Legislature to enact as a statute, or to authorize the Board of Health to establish locally, for we are of opinion that the statute under which the board assumed to act is not broad enough to give them this authority.

"The statute in question does not give the Board of Health power to make regulations as to all matters affecting public health. If the Board should be certain that the smoking of cigarettes by boys affects their health injuriously it would have no power to make a regulation forbidding the smoking of them by boys under a certain age or the sale of them to such boys. It has no power to make general regulations as to conduct or practices injurious to health which, if indulged in by persons, affect the health of the public. The statute gives the Board jurisdiction to deal with 'nuisances, sources of filth and causes of sickness within its town.'

"Plainly the milk in question was not a nuisance or a source of filth. We are of opinion that, within the meaning of the language of the statute, milk kept in a vessel, as this was kept by the defendant, was not a 'nuisance, source of filth or cause of sickness,' which gave the Board of Health jurisdiction to take any action or make any regulation under the revised laws.

"The regulation in the present case has no reference to property in connection with its removal from one city or town to another. Nor is pure milk such an article as is referred to in the statute. We are of opinion that this part of the section does not authorize a regulation as to the sale of milk kept and sold in the manner that is disclosed in this case."

This decision seems of considerable importance, not merely as affecting the case in question, but as a precedent in defining the limits of authority of boards of health. It is of course a matter of law about which there is no further discussion. The decision expressly does not consider the constitutionality of regulating the milk traffic by legislative enactment. So far as the dip-tank is concerned, if it be determined a menace to public health, its use can still be forbidden by statute. It may well be that this decision will serve to bring to a focus legislative action on the whole subject of regulation and control of the milk supply, not in Boston alone, but throughout the Commonwealth of Massachusetts.

## WORK OF THE PHILIPPINE HEALTH BUREAU.

THE eleventh annual report of the Bureau of Health for the Philippine Islands, recently published under date of Aug. 10, 1910, covers the period from July 1, 1909, to June 30, 1910. A preliminary general report by Dr. Victor G. Heiser, director of health, calls particular attention to the completion during that year of the Philippine General Hospital at Manila and of a hospital at Culion; to the beginning of work on the Southern Islands Hospital at Cebu, on hospitals at Bontoc and San Lazaro, on a sanatorium at Sibul Springs and on a tuberculosis camp near Manila; and to the obtainment of funds for the

erection of hospitals at Tuguegarao, Butuan, and other cities in the archipelago. A training school for male nurses has been established at Manila, and the school for female nurses has been enlarged and its work extended. A manual of simple remedies has been issued in five languages for popular distribution. It is announced that beriberi has been eradicated from Culion, and that all known cases of leprosy in the islands have been segregated except in the province of Moro.

The remainder of the report deals with details of these and other aspects of the work of the Bureau. An appendix contains numerous tabulated statistics. The volume concludes with a series of seventeen attractive full-page engravings illustrating sanitary improvements made in various parts of the Philippines, and the work of the several hospitals and colonies.

The entire report is of great interest, not only for the story which it tells, but as an example of the promptness, zeal and efficiency with which occidental methods and institutions have been introduced and established in oriental communities which fifteen years ago were relatively uncivilized or even barbaric.

## EFFICIENCY OF WORK ON MONDAY.

IT is probably a common human experience that it is harder to go to work Monday morning than on any other day in the week. A French physician has recently explained this phenomenon as due to psychomotor inertia following the rest of Sunday. He finds that the efficiency curve of work rises sharply to a maximum on Tuesday, then gradually declines through the remainder of the week to a minimum on Monday. Whether or no this physiologic explanation be sound, it is at least more creditable to mankind than the customary one of innate laziness. So many varying factors enter into the efficiency of a given day's work by any given person that the accurate determination of a constant value should seem to be matter of the greatest difficulty. It may wickedly be suggested that perhaps physicians are the gainers by their frequent custom of resting no more on Sunday than on other days of the week.

## MEDICAL NOTES.

NEW YORK POST-GRADUATE PLANT. — The New York Post-Graduate has plans and descriptions of its new school and hospital at the International Hygiene Exhibit at Dresden, Germany.

A GERMAN DISTINCTION FOR DR. WELCH. — Report from Berlin states that the German Emperor has recently conferred upon Dr. William Henry Welch, professor of pathology at Johns Hopkins University, in Baltimore, the crown order of the second class. This decoration is considered in Germany a high mark of distinction.

TYPHOID AT OTTAWA. — It is reported that typhoid fever has been epidemic for some time at Ottawa, Canada. Since the first of January, there are said to have been over 900 cases of the disease there, with 51 deaths.

HEALTH OF TROOPS IN TEXAS. — Report from Washington, D. C., on April 5, states that health conditions are excellent among the United States troops now in camp along the Mexican frontier near San Antonio, Texas. The percentage of sickness in the entire force at present in the field is less than five tenths. Thus far there has not been a single case of typhoid fever among the troops.

STEAMSHIP "VERONA" QUARANTINED AT PHILADELPHIA. — Report from Philadelphia on April 4 states that the Italian steamship *Verona*, which reached that city on April 2 from Genoa and Naples with over eight hundred passengers, was held there in quarantine on account of two suspected cases of smallpox among immigrants on board.

HEALTH RECORD OF A PENNSYLVANIA FAMILY. — The Philadelphia *Record* reports a remarkable instance of family immunity from death in the case of Mr. and Mrs. Philip Biermann, of Shenandoah, Pa., who will shortly celebrate their golden wedding. Eleven children, seven boys and four girls, have been born to them, all of whom are living. There has not been a death in the immediate family in forty-eight years. There are now thirteen grandchildren. Mr. Biermann is seventy-three years old and his wife sixty-nine.

SHIP'S PHYSICIAN STABBED BY A PATIENT. — Report from London states that Dr. Vogelherr, ship's physician on board the liner *George Washington*, which reached the port of Plymouth, England, on April 6 from New York, received during the voyage a serious stab-wound of the lung from an insane second-class passenger whom he was attending. The doctor is said to be doing well. His injury illustrates one of the incidental risks of the profession.

FIRE IN PHILADELPHIA HOSPITAL. — It is reported from Philadelphia that on the night of

April 6, the laundry building of the Philadelphia Hospital was almost completely destroyed by fire. In the fear that the flames might spread to the adjacent ward for incurable tuberculosis, two hundred patients were temporarily removed thence in cots, but returned after the fire was under control. The money loss is estimated at $100,000.

Publication of Local Health Ordinances. — The weekly health report for March 24 of the United States Public Health and Marine-Hospital Service contains a letter from Surgeon-General Wyman which, on March 4, was sent to the health officer of each city in the United States having a population of over twenty-five thousand. This letter requests every such officer to forward to the Bureau "copies of any ordinances or regulations relating to public health administration" enacted or promulgated in his municipality since Jan. 1, 1910, and in future to forward copies of such ordinances and regulations as soon as passed. It is the intention of the Bureau to print these local rules and regulations in its public health reports, in order to make them easily accessible for study or imitation by health officials in other communities throughout the country.

## BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, April 4, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 45, scarlatina 42, typhoid fever 4, measles 169, smallpox 0, tuberculosis 57.

The death-rate of the reported deaths for the week ending April 4, 1911, was 19.15.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, April 8, 1911, was 290, against 274 the corresponding week of last year, showing an increase of 16 deaths, and making the death-rate for the week, 21.95. Of this number 148 were males and 142 were females; 278 were white and 12 colored; 174 were born in the United States, 110 in foreign countries and 6 unknown; 64 were of American parentage, 177 of foreign parentage and 49 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 45 cases and 7 deaths; scarlatina, 50 cases and 2 deaths; typhoid fever, 6 cases and 2 deaths; measles, 134 cases and 1 death; tuberculosis, 90 cases and 36 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 25, whooping cough 5, heart disease 33, bronchitis 7. There were 17 deaths from violent causes. The number of children who died under one year was 48; the number under five years, 64. The number of persons who died over sixty years of age was 96. The deaths in public institutions were 131.

A Centenarian. — Orson W. Hayward, who died at Waterbury, Conn., in April, was reputed to have been born on March 18, 1810, in Charlestown, Mass. He removed from Boston to Waterbury in 1849.

Fine for Selling Impure Butter. — In the District Court at Dedham, Mass., on April 3, a storekeeper of Readville, Mass., pleaded guilty to the charge of selling impure butter and was fined $25.

Appointment of Dr. Theobald Smith. — It is announced that Dr. Theobald Smith, professor of comparative pathology in Harvard University, has been appointed visiting professor at the University of Berlin for the second half of the academic year 1911–12.

Bequests in Medical Charity. — The will of the late Mrs. J. C. White, of Boston, which was filed on April 7, at the Suffolk Probate Court, contains bequests of $500 each to the Cullis Home for Consumptives and the Boston Floating Hospital, and one of $250 to St. Monica's Home, Roxbury.

Report of the Lawrence Hospital. — The recently published thirty-fifth annual report of the Lawrence (Mass.) General Hospital and Children's Home describes the work of these institutions for the year ending Sept. 30, 1910. During this time 1,156 patients were admitted to the hospital, an increase of 14 over the preceding year. Sixty-four cases were received in the Anti-Tuberculosis Day Camp. There are at present 34 pupils in the training school, from which 8 nurses were graduated in 1910.

Report of Boston Lying-In Hospital. — The seventy-eighth annual report of the Boston Lying-In Hospital, just published, presents the record of its work for the calendar year 1910. During this time 829 mothers and 828 infants were cared for in the house, and in the Out-Patient Department 2,007 mothers and 2,022 infants. Among the patients in the house, there were 24 cases of eclampsia and 17 of placenta previa. Cæsarean section was performed on 18 patients,

on one of them for the fifth time. There was one case of triplets during the year. The nurses' training-school has graduated 32 pupils in 1910.

EXAMINATION FOR REGISTRATION IN DENTISTRY. — At the latest examination held in Boston on March 1, 2 and 3, before the Massachusetts State Board of Registration in Dentistry, of seventy candidates, only fourteen passed. This is said to be the largest percentage of failures ever recorded. Many of the applicants were not graduates of any dental school.

APPOINTMENT OF DR. KELEHER. — It was announced last week that Dr. William Henry Keleher, of Woburn, Mass., has been appointed medical examiner of the district comprising Woburn, Winchester, Lexington and Burlington, Mass. Dr. Keleher, who received the degree of M.D. from the Harvard Medical School in 1892, is a Fellow of The Massachusetts Medical Society.

A YOUTHFUL BRIDE AND MULTIPARA. — Mrs. Louis C. Chevigney, who died last week in Brockton, Mass., at the age of sixty-four, is said to have been married when she was only twelve years old. At the age of twenty-five she had had eight children, when she was thirty-five her first grandchild was born, and before she was sixty her first great-grandchild. She is survived by five of her own children, two daughters and three sons, two of the latter being physicians.

SEIZURE OF IMPURE CONFECTIONERY IN PROVIDENCE. — In the issue of the JOURNAL for March 30, we noted the seizure at Providence, R. I., on March 23, of 1,000 lb. of jelly beans, alleged to contain talcum. On April 3, in the same city, was made a second seizure of 1,000 lb. of jelly beans and 800 lb. of cocoa almonds, also alleged to contain talcum, shipped to Providence from a manufacturing firm in Boston.

PROHIBITION OF PUBLIC DRINKING-CUPS IN RHODE ISLAND. — In last week's issue of the JOURNAL we noted the unanimous passage by the House of Representatives of the Rhode Island General Assembly of a bill prohibiting the use of common public drinking cups in that state. On April 5, this measure was unanimously passed by the Senate also. The execution of the new law is placed in the hands of the State Board of Health.

NEEDS OF THE PORTLAND CHILDREN'S HOSPITAL. — On April 4, it was announced by the trustees of the Portland (Me.) Children's Hospital that unless private subscriptions to the amount of $25,000 can be obtained before May 1, the hospital must be closed on that date. This situation is due to the fact that the governor of Maine has vetoed the bill passed by the State Legislature providing the usual annual appropriation, upon which the hospital is dependent for paying its current expenses. It is to be hoped that the present deficiency may be promptly met by generous charitable contributions, in order that such closure of the institution may be avoided.

## NEW YORK.

STATE DEPARTMENT OF AGRICULTURE. — Dr. John G. Wills, of Chateaugay, Franklin County, has been appointed by Commissioner Pearson chief veterinarian in the State Department of Agriculture, in succession to Dr. J. F. Devine.

APPOINTMENT OF PROF. ALEXANDER SMITH. — Prof. Alexander Smith, for twelve years past the head of the Chemical Department of the University of Chicago, has been appointed professor of chemistry in Columbia University, in succession to Dr. Charles F. Chandler, who is about to retire from that position after forty-seven years' service. Professor Smith, who was born in Edinburgh, was graduated from the University of Edinburgh and obtained the degree of Ph.D. at Munich. He is at present president of the American Chemical Society.

MENINGITIS AMONG GREEK IMMIGRANTS. — On April 2 two transatlantic steamships arrived at quarantine, on each of which two Greek steerage passengers had died from cerebrospinal meningitis during the voyage. Health Officer Doty has now received word, however, that the medical authorities at Piraeus have been instructed to hold for observation for ten days all emigrants for this country. He has been informed also that the meningitis epidemic in Greece is diminishing.

BEQUEST TO THE PRESBYTERIAN HOSPITAL. — Among other charitable bequests in the will of the late Mrs. Benjamin Welles, of New York, is one of ten thousand dollars to the Presbyterian Hospital, to establish a fund, the income of which, equally divided, is to be used "to brighten the lives of the nurses and patients."

LATEST FATALITY FROM WASHINGTON PLACE FIRE. — On April 7, in St. Vincent's Hospital, the one hundred and forty-fourth and probably last victim of the Washington Place fire died, a girl who jumped from the ninth floor of the burning building. At that date the relief fund for the

sufferers from the fire amounted to over $82,000, and it is expected that it will be still further increased by the proceeds from a number of benefit performances.

Prosecution of a Christian Science Healer. — At the instance of the County Medical Society, another Eddyite healer has been arrested on the charge of practicing medicine illegally, and held in $500 bail. The society thought it had a test case when, a few weeks ago, the healer, Cole, was held by Magistrate Freschi for trial in Special Sessions, a court which for many years has dealt with cases involving a construction of the medical statutes. Later, however, Cole's council, ex-District Attorney Jerome, succeeded in getting the case transferred to the Court of General Session, where there will have to be a trial by jury, with the delay incident to congested calendars. In both these instances the evidence was secured for the society by a woman detective who represented herself as a patient.

A Centenarian. — The death of another centenarian is reported from that temple of longevity, the Home of the Daughters of Jacob, on East Broadway. Mrs. Esther Davis, a Russian Jewess, died there on April 5, at the advanced age, according to her friends, of one hundred and seventeen years, a statement which probably cannot be received with implicit reliance. Although she did not come to this country until thirty-five years ago, she became a candy peddler in Hester Street, and she continued actively in this occupation until she was one hundred and twelve years old, if her reputed age is accepted.

1. Thomson writes an interesting paper on pneumococcus infections and closes with some remarks on the treatment of pneumonia. He considers it important to avoid bodily movement carefully. In no acute disease, he says, is removal to a hospital over the rough street pavements so often fatal. The best stimulant for heart failure in pneumonia is camphor given hypodermically in 7½-gr. doses dissolved in a syringeful of sterilised olive or almond oil and repeated in two hours if necessary. For the severe pleuritic pain at onset, a single hypodermic injection of morphia (gr. ¼–½) over the seat of the pain is of great service. The writer believes that the mortality from pneumonia can be reduced by the use of carbonate of creosote. The extreme susceptibility of the pneumococcus to the faintest trace of carbolic acid may allow of this preparation being regarded as a true blood germicide. He gives this drug in 15-gr. doses every two or three hours in a specially prepared emulsion.

4. Cornwall emphasizes a few important points in the treatment of arthritis deformans. In the first place, one should find out whether chronic putrefactive toxemia is an etiologic factor or not. If it is, the diet should consist of sour milk, cereals, fats, vegetables and fruits. Feeble patients should not be stuffed, especially with putrefiable proteids. On the other hand, it is important to "feed up" in cases with debility and malnutrition. Potassium iodide is of value in some cases, but the salicylates are worthless in all cases. [L. D. C.]

1. Hunner cites a series of cases in which, when all other sources of infection could be ruled out, the tonsils seemed to be the primary focus of a chronic urethritis or ureteritis; and which were cured after removal of the diseased tonsils. The series is a small one, but very suggestive.

3. Glueck concludes that there is no psychotic entity which can be diagnosed as a traumatic psychosis without a history of a definite relation of the mental disturbances to a preceding trauma of the head, and, contrary to Kreuser's views, even what he terms endogenous psychoses can be brought on by head injuries, as the author's para-

noid and hypomanic cases show. The prognosis is favorable in the cases which show acute mental disturbances, such as acute delirious or confusional states, while in the so-called endogenous psychoses the prognosis is extremely bad. The author's hypomanic patient is still insane, six years after the injury, and the paranoid patient has shown no improvement for seven years.

4. Lockwood asserts that the recent improvement in surgical statistics in gastric ulcer, whereby a 10% mortality is the rule, is not only due to improvement in surgical technic, but also to the increased wisdom of the physician in calling in surgical help earlier, and in better selected cases. He rates mortality in uncomplicated gastro-enterostomy by a skilled surgeon, 2 to 3%; by the average surgeon, 6 to 8%; and the general operative mortality, 10 to 15%. The end results of medical treatment vary much with different men, but a fair average seems to be about 70% of cures, 17% of relapses and about 50% permanently cured, as opposed to the 90% of clinically cured cases reported by most authors. There should be no such thing as exclusively medical treatment. The better results of the present day are due to closer harmony of opinion as to treatment between medical and surgical men. Acute uncomplicated ulcers are best treated medically. Relief is usually prompt and lasting. [E. H. R.]

BULLETIN OF THE JOHNS HOPKINS HOSPITAL.

MARCH, 1911.

1. *MALLORY, F. B. *Cirrhosis of the Liver. Five Different Types of Lesions from which it may Arise.*
2. *MCCRAE, T. *Typhoid Spine, with the Report of Two Additional Cases with Bony Changes in the Vertebræ.*
3. PARKER, H. P., AND HAZEN, H. H. *Erythema Multiforme Iridis during the Course of Typhoid Fever.*
4. *WOOLLEY, P. G. *Acute Tuberculous Endaortitis.*
5. GATCH, W. D. *Report of a Case of Extensive Tierach Skin Graft.*
6. *THAYER, W. S., AND MORRIS, R. S. *Two Cases of Congenital Hemolytic Jaundice with Splenomegaly. Observations on Hemolytic Jaundice.*

1. Mallory, in an article clearly and concisely presented, and illustrated with beautiful plates, describes five types of lesions which may terminate in cirrhosis of the liver. The first, toxic cirrhosis, is due to toxins present in the circulation. It is characterized by necrosis of the cells around the hepatic veins, so-called central necrosis. It is acute and is often a terminal infection. Severe degrees of this constitute the condition known as acute yellow atrophy. The second type he calls infectious cirrhosis and is due to the presence of bacteria in the lesions. Infection is usually through the bile ducts. It is a rare chronic condition. The lesion spreads from the portal vessels toward the hepatic veins. There is extensive inflammatory reaction and increase of fibrous tissue, with a great increase in the size of the liver. The third type is pigment cirrhosis, occurring in cases of hemochromatosis. It is due to mechanical causes. Endothelial leucocytes filled with pigment collect in and block up the lymphatic vessels and spaces. There is an increase in connective tissue and in the size of the liver. It is a very chronic condition. The fourth type is syphilitic cirrhosis. Immense numbers of the treponemata are present in the liver; there is a great increase in fibrous tissue and in the size of the liver. The fifth and last type is alcoholic cirrhosis. Here the cells first affected lie most commonly in the region of the portal vessels. There is hyaline degeneration of the liver cells, often fatty infiltration, and active regeneration of connective tissue.

2. McCrae reports two additional cases of typhoid spine. The findings of recent years have finally settled the much-disputed question of the nature of this condition and show that it is a true spondylitis. The various changes which suggest an actual organic involvement of the spine itself are (1) local swelling, which has been frequently noted; (2) actual changes in the normal curves of the spine; (3) evidence of involvement of nerve roots; (4) radiograms and (5) local suppuration. Treatment is chiefly prophylactic — to warn the convalescent patient against too severe strain on the spine. The immediate treatment is by a plaster jacket or other fixation apparatus.

4. Woolley reports the details of a rare case of acute tuberculous endaortitis with a summary of previously reported cases.

6. Thayer and Norris report in detail two cases of congenital hemolytic jaundice with splenomegaly, with further observations on the condition and a review of the work previously done on it, particularly on the peculiar conditions associated with it — fragility of the red corpuscles and the presence of the reticulated red blood corpuscle as shown by vital staining methods. They go over the symptomatology of this condition and compare it with acquired hemolytic jaundice. This latter presents itself in three forms: (1) those cases simulating cholelithiasis; (2) those simulating pernicious anemia with jaundice; and (3) those simulating a chronic infectious cholangitis. They consider the pathological anatomy and pathogenesis of this condition. As to when hemolysis takes place, evidence seems to favor the view that this occurs in the circulating blood; the cause of the jaundice itself seems to be in the blood rather than in the liver.

[J. B. H.]

JOURNAL OF INFECTIOUS DISEASES.

MARCH, 1911.

1. SWINGLE. *The Transmission of Trypanosoma Lewisi by Rat Fleas.*
2. *GRAHAM. *The Influence of Ether and Ether Anesthesia on Bacteriolysis, Agglutination and Phagocytosis.*
3. WHITE AND ZEUBLIN. *The Influence of Fresh and Autolyzed Organ Extracts on Experimental Tuberculosis.*
4. DAVIS. *The Immunological Reactions of Oidiomycosis in the Guinea Pig.*
5. JACKSON. *Classification of the B. Coli Group.*
6. *KENDALL AND EDWARDS. *A Method for Determining the Germicidal Value and Penetrating Power of Liquid Disinfectants.*

2. Ether produces no effect upon bacteriolysis or agglutination, but causes a marked depression in phagocytosis. This was demonstrated with many of the organisms. The anesthetic was given to patients, free from infection, who were undergoing simple operations. The depression is due apparently to the action of the ether directly on the leucocytes and serum, possibly from the fat-solvent action of the ether. The instability of this ether union is demonstrated by the removal of the inhibitory action where air is passed through the mixture. A similar counteraction is produced by injections of lecithin in vitro, and by rectal injections of olive oil in vitro and in vivo.

6. The authors have devised a simple and apparently trustworthy method of determining the penetrating properties of liquid disinfectants. The test material consists of agar cylinders of definite diameter, infected, while liquid, with B. coli. Measured sections of these cylinders are placed in the disinfectant. At stated intervals they are removed and the central core extracted. These are washed in sterile water and incubated in dextrose fermentation tubes. The formation of the gas indicates that the disinfectant of that strength has not penetrated to the center of the cylinder in that given time. The application of this method has proved satisfactory in the hands of the writers. [L. H. S.]

ANNALS OF SURGERY.

FEBRUARY, 1911.

1. ELSBERG, C. A. *Anesthesia by the Intratracheal Insufflation of Air and Ether.*
2. *ELIOT, E., AND CORSCADEN, J. A. *Intussusception, with Special Reference to Adults.*
3. WILSON, L. B. *Diverticula of the Lower Bowel; Their Development and Relationship to Carcinoma.*
4. MILLER, R. T., JR. *On the Coincidence of Volvulus and Real or Simulated Strangulated Hernia.*
5. *MARRO, A. *The Restoration of Fecal Continence after Iliac Colostomy.*

2. The authors have studied 300 cases of intussusception collected from the literature. Many phases of the subject are discussed and the article is concluded by case epitomies. There were 23 cases in which intussusception was associated with trauma, 60 cases with benign tumor, 40 with malignant tumor, 29 cases with Meckel's diverticu-

lum, 2 cases with foreign bodies, 19 cases with ulceration (typhoid, dysentery, tuberculous, simple inflammatory). Attention is directed to the varied symptomatology of intussusception in adults, and symptoms of several etiologic groups are considered in detail. Disappearance of the tumor as a result of rectal infections may mean but partial reduction, and after a brief respite acute symptoms may recur. The general condition of the patient is then less capable of overcoming the shock of inevitable operation. The results of various operative procedures are presented in a table. With both intussusceptum and intussuscipiens necrotic, resection is imperative, followed in adults by ether anastomosis or enterostomy. In infants the latter procedure should never be practiced With the intussuscipiens viable the intussusceptum may be resected by splitting the wall of the former. The results are good.

5. The principle of Marro's operation to restore fecal continence after iliac colostomy is in conducting the mobilized proximal end of the bowel upward through a subcutaneous tunnel parallel to the external border of the rectus muscle to an external position above the belt line. The bowel is carried horizontally from a median incision beneath the rectus to a point just external to it. This is accomplished by a short vertical incision whose upper end is not higher than a line joining the iliac crests. The bowel is then carried vertically upward through a subcutaneous tunnel and permitted to protrude at a point above the belt line. Fecal continence is thus doubly insured: first, by angulation of the bowel in the submuscular and subcutaneous tunnels and, secondly, by compression of the bowel in its subcutaneous tunnel by the waist band of the drawers or other belt. [T. W. H.]

### Surgery, Gynecology and Obstetrics.

### March, 1911.

1. MacCarty and McGrath point out that the average age at which complete obliteration of the appendix occurs is thirty-four and six-tenths years. The tip may be obliterated as early as five to ten years. In these series 90% of the carcinomata occurred in the tip of the appendix, and in partially or completely obliterated appendices. With this in mind, surgeons should always remove partially or completely obliterated appendices, instead of leaving them for nature to take care of the process, which probably is not a normal physiologic involution, as was formerly supposed. Obliteration seems to occur as the result of an inflammatory process, as shown by its histology, duration of the process and high frequency in appendicitis. Carcinoma may occur at practically any age. Carcinoma of the cecum probably arises from the appendix only in a very small percentage of cases.

4. Ewing has been unable to find satisfactory evidence that any considerable portion of tumors of the testicle arise from the stroma or tubules of this organ, but evidence points to the conclusion that with relatively few exceptions tumors of the testicle belong in the embryonal class and that the great majority or possibly all of these embryonal tumors are of teratomatous origin. He concludes that teratoma testis arises from sex cells in the neighborhood of the rete whose normal development with spermatogonia has been suppressed, but whose potencies remain intact and ready to express themselves in the various forms of simple or complex teratomata.

5. Seelig and Gould have demonstrated experimentally that 90 and 95% alcohol have far greater penetrative power to kill bacteria than 70%, which has previously been advocated. Also that iodine is one of the most powerful antiseptics because of its power of penetration or osmosis. Likewise, alcoholic solutions of iodine are more efficient than Harrington's solution. The efficiency of any germicide depends, they think, on its power of penetration more than on any other factor.

6. Schrager writes of hernial tuberculosis that the French deserve the credit for the most important literature on this subject. Hernial tuberculosis is most common in children. The male is three times as often affected as the female, for the sole reason that hernia is more frequent in the former. The cause of hernial tuberculosis is largely, though not entirely, that of peritoneal and intestinal tuberculosis. The general opinion is that in 70% of the cases it is merely the expression of a peritoneal tuberculosis and in the remainder of the cases it is associated with tuberculosis of other organs, particularly the genitalia. As a rule both sac and contents are tuberculous. The four symptoms on which a diagnosis can often be made are pain, physical changes in the hernia, irreducibility and fluid in the sac. In one series of 115 cases primary union occurred in 98 cases. In 8 cases fistulæ formed which were obstinate to treatment. [E. H. R.]

### The Practitioner.

### March, 1911.

1. *Gould, A. P. *Cancer and the General Practitioner.*
2. *Bashford, E. F. *The Obligation imposed upon the General Practitioner by the Development of the Experimental Investigation of Cancer.*
3. Rigby, H. M. *Some Points in the Diagnosis and Treatment of Cancer of the Breast. Seventy-eight Cases Treated by Operation.*
4. Dixon, W. E. *Some Considerations on the Absorption and Excretion of Drugs.*
5. Stark, A. C. *Some Clinical Uses of Sodium Salicylate.*
6. Hawthorne, C. O. *Some Cases of Infective Endocarditis.*

10. Liddell, J. *The Nervous Phenomena Occurring in Chronic Mucous Colitis.*
11. Styles, R. C. *Spengler's Differential Staining Methods for Tubercle Bacilli.*
12. *Abrahams, A. *Athletics and the Medical Man.*
13. Wynne, J. D. *Dr. Johnson and the Medical Profession.*

1. Gould urges that all practitioners send to the operating surgeon the histories of their cancer cases after operation.

2. Bashford describes the extent, scope and aims of the various investigations now being made into the nature of cancer. He urges, however, that, until a specific cure is discovered, that every practitioner urge the earliest possible removal of all lesions that have the remotest chance of being cancerous.

9. Henry describes in great detail an interesting case of malignant endocarditis in which the pneumococcus was the infecting organism and which was remarkably benefited and practically cured by injections of a polyvalent pneumococcic vaccine.

12. Abrahams gives an interesting paper on the so-called dangers of athletic exercises. These dangers he discusses, and demonstrates the fallacy of most of them. The man to whom athletics is most dangerous is the experienced athlete who goes into a race without proper training; the amateur and the school boy are rarely able seriously to harm themselves through inability to use up all their strength and energy in one effort. In certain instances, as in an eight-oared crew, this is different; here the weakest member must keep pace with the strongest. For this reason he unreservedly condemns school-boy rowing. He discusses in turn the possible ill-effects which may result to the heart, kidneys, muscles, joints, stomach. His views on training are refreshingly sane. [J. B. H.]

THE INDIAN MEDICAL GAZETTE.

JANUARY, 1911.

2. *HEHIR, P. *Historical Note on Cholera in India.*
3. ANDERSON, S. *Arrows and Arrow-Wounds in Manbhum.*
4. SEN, H. *The Health of a Bengal District.*
5. STEWART, A. D. *Two Cases of Ascariasis.*
6. *HEFFERNAN, P. *A Case of General Paralysis of the Insane in a Native of India.*
7. MUIR, E. *The Ipecacuanha Treatment in Liver Abscess.*
8. STEPHEN, L. P. *A Case of Traumatic Rupture of the Prostatic Urethra.*

2. Hehir quotes an interesting letter of Robert de Mobilibus, written from Madura on April 22, 1609, describing under the name of *Mordechien* a virulent disease then epidemic in that kingdom and apparently identical with Asiatic cholera. It is known that the Portuguese of Goa called cholera by the name *Mordechien* as early as 1563. The author further quotes a letter of Father Martin, a Jesuit missionary in Madura, describing another epidemic of *Mordechien* in 1700, and the quaint methods attempted for its cure.

6. Heffernan reports with interest a case of general paralysis in a native Indian, as a rare exception to the usual immunity of such natives to this parasyphilitic process. [R. M. G.]

FEBRUARY, 1911.

2. FOULKES, T. H. *A Speculation on Diabetes Mellitus. (Preliminary note.)*
3. *ROGERS, L. *Gleanings from the Calcutta Post-Mortem Records. IV. Cirrhosis of the Liver.*
4. SUHRAWARDY, H. *Pancreatic Cysts.*
5. MUIR, E. *Treatment of Kala-Azar by the Hypodermic Injection of a Solution of Quinine Sulphate.*
6. ROBERTS, J. R. *A Method of Performing Gastro-Jejunostomy and Intestinal Anastomosis by a Single Row of Sutures.*

3. From a careful comparative pathologic study of 333 cases of cirrhosis of the liver observed at autopsy in the Calcutta Medical College between 1873 and 1909, Rogers derives the following conclusions:

(1) Cirrhosis of the liver is several times as frequent in Calcutta among natives of India as it is in a temperate climate, but is not especially common among European residents.

(2) Although Mohammedans are forbidden the use of alcohol by their religion, cirrhosis is only slightly less frequent among them proportionately than among Hindus, who drink wine.

(3) One fifth of the cases of cirrhosis in Calcutta are secondary to kala-azar.

(4) There is no evidence that malaria ever produces cirrhosis of the liver in Calcutta.

(5) Hanot's hypertrophic cirrhosis is rare in Calcutta.

(6) In Calcutta cirrhosis of the liver is so frequently associated with chronic dysentery, usually of the amebic type, as to suggest that the fibrosis of the liver is secondary to the bowel ulceration.

(7) Chronic inflammatory change, due to bacterial infection or toxic absorption through ulcers of the gastro-intestinal tract, is also a likely cause of cirrhosis of the liver.

(8) Leucocytosis is common in the ordinary type of cirrhosis of the liver, a high degree being of very bad prognostic significance. On the other hand, leucopenia points to a cirrhosis secondary to kala-azar. [R. M. G.]

MARCH, 1911.

8. Stursberg, H. *Investigations on the Kind and Cause of Reflex Vascular Disturbances in Syringomyelia.*

1. Müller's article on the vagus nerve is a complete one from the point of view of anatomy and physiology. It is impractical to review such an article, but it is worth while to have it as reference for any one who is interested in looking up any questions on the vagus nerve.

2. Scheidemandel has performed 1,212 Wassermann tests during the past two and one-fourth years. His technic has been that originally pursued by Wassermann, in whose laboratory he learned it. He finds it convenient to group the results under four heads. Complete checking of hemolysis and almost complete checking he calls strongly positive. Incomplete checking he calls weakly positive, and he calls doubtful the cases in which there is moderate hemolysis. If one considers only the strongly positive cases as diagnostic, the test is specific in 99% of the cases. In the doubtful positive cases and weakly positive cases the test is not nearly as specific. He warns against using one negative test for diagnostic purposes. Bile-stained serum is unsatisfactory. He found that the kind of complement was next in importance to the kind of antigen used. He urges that all laboratories use the original Wassermann method and the same antigen. [C. F., Jr.]

## Miscellany.

### HEALTH INSPECTION IN FACTORIES.

At a meeting of the Association of the State Inspectors of Health, the members of the association passed the following resolve:

*Whereas*, The Association of the State Inspectors of Health of Massachusetts, after carefully considering the report of the Massachusetts State Commission appointed last year to investigate the general subject of industrial inspection, find that (1) the commission's presentation of the subject of health inspection in factories as carried on by the State Inspectors of Health under the State Board of Health is incomplete, (2) contains inaccuracies and on the whole shows (3) a superficial familiarity on the part of the commission with the work of the State Inspectors of Health. Therefore be it

*Resolved*, That the members of the association deeply regret this lack of knowledge on the part of the commission, and the absence from the report of any statement showing the actual work done by the State Inspectors of Health, and the great number of changes that have been made to improve the sanitation of factories and workshops as the result of written orders and recommendations.

*Resolved*, That the members of the association especially regret this omission not so much on account of the injustice done to the State Inspectors of Health, but on account of the reflection it casts on the state of Massachusetts and the erroneous impression of the work which will be conveyed wherever that report may circulate.

The Association of the
State Inspectors of Health.
By their committee,
(Signed) Harry Linenthal.
Adam S. MacKnight.
Elliott Washburn.
Lyman A. Jones.
Wm. W. Walcott.

## Correspondence.

### THE BEST ROUTE TO SEE THE WONDERS OF THE WESTERN SLOPE.

Boston, April 3, 1911.

*Mr. Editor:* As members of the American Medical Association are to have peculiar inducements offered them for visiting the Pacific coast this summer, may I be permitted to call attention in your columns to a route that will allow the most interesting places in the western part of our country to be seen under very favorable conditions.

The first point of interest will naturally be the Grand Canyon of Arizona, although a few may wish to stop over one train to see the petrified forests of Arizona near Holbrook. At least one day should be spent at the canyon. On reaching southern California, visits can be made to Redlands, Coronada Beach, etc., on the way to Los Angeles.

On leaving the latter city those desiring to visit the Yosemite Valley can go via Bakersfield and Fresno to Merced, where the branch line leaves for the valley. A pleasanter way, however, would be the coast line via Santa Barbara, Monterey, San José to Merced and thence into the Yosemite. This route is longer, but allows one one to see much that the other does not. The Yosemite and the Big Trees are among the wonders of this continent and are well worth seeing.

San Francisco comes next in order and is always interesting to an Eastern man. He will be sure of a hearty welcome and will see much to entertain him for some days. Leaving that city by the "Shasta Route," the next place of interest will be Portland, Ore. Next come Tacoma and then Seattle. From the latter place steamers can be taken for the Alaska trip.

The most interesting portion of the Canadian Rockies lies between Seattle and Banff, and by returning to Seattle from Banff an opportunity is given to see the Yellowstone Park, the third of the trio of wonders in the western country. Time from Seattle to Banff is about eighteen hours and the round trip is $30.

Leaving Seattle by the Northern Pacific Road gives one an opportunity to visit the Yellowstone Park, requiring about a week. From the Yellowstone one can return east via Ogden and Salt Lake City, or via St. Paul and the Great Lakes, or from St. Paul via Chicago.

The above route enables one to see the wonders of the western slope and as many of the lesser places of interest as he cares to take in. The trip is an ideal one for this country and will well repay those who take it or any portion of it.

Very truly yours,
GEORGE W. GAY, M.D.

## PROFESSOR IRVING FISHER'S REPORT ON NATIONAL VITALITY.

BUFFALO, N. Y., March 20, 1911.

*Mr. Editor:* In your editorial under the above heading in your issue of March 16, you say that "there seems a slight suggestion of personal animus" in my *examination* of Professor Fisher's *report*, which appeared in *Lancet Clinic* of Feb. 18. This is a mistake. Professor Fisher is, I know, an agreeable gentleman, and an extremely able mathematician, although I do not think that I have ever met him. His diatribes on dietetics and vital statistics, however, in my opinion, do a great deal of harm, because some persons imagine that he is a physiologist and take his ipse dixit seriously. One of his dogmatic assertions upon a very important question of physiological chemistry was submitted by me to two authorities of the first rank with the result that one of them denied its accuracy and the other said that he did not know what the learned professor meant! Professor Fisher's knowledge of vital statistics is well exemplified by his statement on page 2 of *National Vitality* that "the larger the city, the higher the death-rate." What better evidence could be furnished that the gentleman has not grasped the elements of mortality figures? I have no personal animus toward Professor Fisher, but I am opposed to his method of giving to the gullible public as facts assertions that any statistician could disprove. This he has done, as I have shown, not only in *National Vitality*, but also in *Costs of Tuberculosis*.

Very truly yours,
LAWRENCE IRWELL.

## TREASURY DEPARTMENT, BUREAU OF PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE.

A BOARD of commissioned medical officers will be convened to meet at the Bureau of Public Health and Marine-Hospital Service, 3 B Street, S.E., Washington, D. C., Monday, May 22, 1911, at 10 A.M., for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health and Marine-Hospital Service. Candidates must be between twenty-two and thirty years of age, graduates of a reputable medical college, and must furnish testimonials from responsible persons as to their professional and moral character. For further information, or for invitation to appear before the board of examiners, address "Surgeon-General, Public Health and Marine-Hospital Service, Washington, D. C."

## SOCIETY NOTICES.

AMERICAN PROCTOLOGIC SOCIETY.—Thirteenth annual meeting, Los Angeles, Cal., June 26 and 27, 1911. Headquarters and place of meeting, Hotel Alexandria, corner Fifth and Spring streets. The profession is cordially invited to attend all meetings.

LEWIS H. ADLER, JR., M.D., *Secretary*,
Philadelphia.

AMERICAN SOCIETY FOR THE STUDY OF ALCOHOL AND OTHER NARCOTICS.—The American Society for the Study of Alcohol and Other Narcotics will hold its fortieth anniversary meeting at Baltimore, Md., April 19 and 20, 1911. The sessions will be held at the Hotel Belvedere.

NEW ENGLAND HOSPITAL MEDICAL SOCIETY.—There will be a meeting of the New England Hospital Medical Society, Thursday, April 20, at 7.30 P.M., Kensington Building, Boylston St. Dr. Anne Worthen will read a paper on "Some Present-Day Interests in Dentistry." All are cordially invited.

MARGARET L. NOYES, M.D.,
*Secretary*.

CANADIAN MEDICAL ASSOCIATION.—The annual meeting of this association will be held in Montreal, June 7, 8 and 9, in the building of the Medical Faculty of McGill University. Inasmuch as the functions connected with McGill convocation and the McGill reunion take place on the two days preceding the meeting of the association, it is expected that the attendance this year will break all previous records in numbers.

## RECENT DEATHS.

DR. CHARLES TALBOT POORE, a prominent orthopedic surgeon of New York, died suddenly on April 4. He was born in New York, of Colonial Dutch ancestry, and was graduated from the College of Physicians and Surgeons in 1866. He had been for many years surgeon to St. Mary's Free Hospital for Children and also consulting surgeon to the Hospital for Ruptured and Crippled. Of late Dr. Poore had confined his practice principally to consulting work.

DR. WILLIAM HENRY DE COURCY, who died on April 6, at Baltimore, Md., was born in 1825. He practiced medicine for a number of years in New York City, but after his retirement lived at Cheston-on-the-Wye, Queen Anne County, Md. He was not married.

DR. JOHN H. SANBORN, who died on April 2, in Newport, R. I., was born at Pittsfield, N. H., in 1835. In 1852 he received the degree of M.D. from Berkshire Medical College, and practiced his profession until the outbreak of the Civil War. He then enlisted as a private in the Third New Hampshire Regiment and served throughout the war with that command. Subsequently he became a surgeon in the United States Army Medical Corps, and remained in that service until 1892. At the time of his retirement from the army he was quartered at Jefferson Barracks, Mo.; but he later removed to Newport, R. I., and resumed the private practice of medicine there. In 1896 he was made city physician of Newport, an appointment which he held till his death. He is survived by two daughters and one son.

DR. HENRY LYMAN SHAW, who died at Boston on April 2, was born in 1838. In 1859 he received the degree of M.D. from the Harvard Medical School, and subsequently served for a time as physician to the Boston Dispensary. In 1861 he was appointed assistant surgeon and in 1864 surgeon to the Massachusetts Charitable Eye and Ear Infirmary, and in 1892 became consulting surgeon to that institution. He was a Fellow of The Massachusetts Medical Society, a member of the American Medical Association, of the American Ophthalmological Society, of the New England Ophthalmological Society, of the Boston Medical Library, and of the Boston Society for Medical Improvement. He is survived by his widow.

## Original Articles.

# SCOLIOSIS WITH MARKED STRUCTURAL CHANGE AND ROTATION.

BY ROBERT SOUTTER, M.D., BOSTON,

*Assistant Surgeon, Children's Hospital, Boston; Orthopedic Surgeon to Long Island Hospital; Surgeon to the Massachusetts State Hospital for Cripples; Assistant Instructor, Orthopedic Surgery, Harvard Medical School.*

MANY things must be considered in the treatment of scoliotic patients that have marked structural change and rotation. The patient is often in a very poor condition and will not stand long and elaborate treatment. Very often the patient has been so shielded at home that the mental condition as well as the physical is not favorable to rigorous treatment. This paper is a plea for the more thorough treatment of stiff scoliotic cases, in many of which absolute correction of the curve seems practically impossible. Simple, flexible and uncomplicated curves are not considered in this paper.

That the rotation may be attached by pressure on the ribs is no longer a theory. Several years ago this was demonstrated by experiments on the cadaver, by Dr. Keene at the Harvard Medical School, the writer and others.[1] The most excellent work of Hoke, Seaver, Hoffa, Eulenburg, Bradford, Schultess, Nicoladoni, Wullstein, Lange, Shans and others have demonstrated the practicability of extensive and thorough treatment in difficult cases of scoliosis. Many problems are still to be solved as to the etiology of scoliosis, and a great deal has been done recently in this direction by Wullstein, Lovett, Bern, Adams, Feiss and others. While this is being done, thorough and systematic treatment of these difficult cases is well worth while, though the etiology in many cases cannot be perfectly traced.

The correction of the curve and overcoming of the rotation are of ultimate importance, but in some cases they are secondary and dependant on a preliminary redistribution of the body weight before actual correction of the deformity can be advantageously undertaken.

The general condition must be improved. Development exercises should be done systematically, all exercises taken in a position which brings a miminum strain on the deformity. This may be accomplished best by suitable machines for the purpose under skilled assistants. It is accomplished also at home to a less extent. The flexibility of the spine in all directions should be increased; having attained this, and improved the general physical condition, the state of mind and endurance of the patient is much better. The periods for eating, for rest and for work should be established with regularity. Correction of the deformity is started during the development and flexibility treatment; later it is carried to a greater extent and the points of greatest deformity attacked more vigorously. Exercises are adjuncts in the treatment and will not take the place of especially adapted corrective machines and apparatus applied to the deformity.

[1] "Study of the Effect of Pressure on the Curve and Rotation of the Spine." Am. Jour. Orthop. Surg., October, 1906.

The advanced case of scoliosis should not be trifled with. In addition to the appliances in which the patient is treated for three to four hours each day, the patient should have apparatus to wear when about, and other apparatus to wear when in bed. The amount of apparatus and the treatment necessary varies with the patient. The apparatus worn at night is made after a certain amount of correction has been attained.

FIG. 1. Form of jacket used for action on rotation; remodeled from plaster torso.

The night and day apparatus must be carefully adapted to the improvement. Corrective jackets follow the other treatment. They may be made by placing the patient in a position of maximum correction (see Fig. 12) by means of carefully applied pressure rods and pads and straps which may be applied to this machine and to others. A cast is made from the jacket applied; it is modeled to obtain the points of correction that were necessarily omitted at the time of applying the plaster to the patient. The patient is kept recumbent and successive corrective jackets applied either from remodeling the cast or from newly applied jackets. The apparatus has large windows (see Figs. 18 and 19), without which the patient could not tolerate the correction resulting from the remodelled cast. Windows in plaster or other jackets may be helpful, but the maximum use of the window in a jacket is obtained by remodelling the plaster torso, the jackets from which could not be tolerated without the windows (see Figs. 1 and 2).

FIG. 2. Notice oblique opening in front to allow a large window on front of right chest; pressure on the left front with corresponding window and behind on the opposite side.

In the forcible correction of curvature, head pull and shoulder pull, varying with the patient, from 100 lb. to nearly 150 or more, facilitates the correction of the curve and the rotation by means of pressure. The apparatus includes the neck whenever possible and the shoulders. While this is not always necessary, a much better purchase on

the spine and consequent better correction is obtained. In some cases inclusion of the head and neck cannot be carried out satisfactorily.

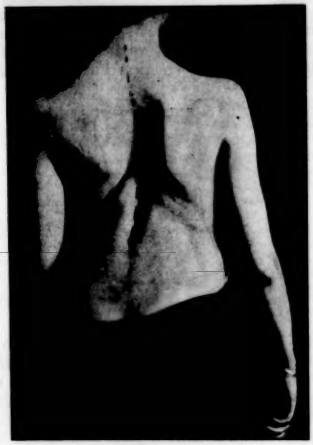

FIG. 3. Long rigid curve. Prominent left hip.

Following two or four months of corrective apparatus, a retentive apparatus is applied (see Figs. 1 and 2), maintaining the full correction in a comfortable way and the patient allowed to

FIG. 4. Two years later very little deformity remains.

go two to six months, when further treatment may be instituted, according to the requirements.

In short, after a thorough course of flexibility and muscular work in corrective machines, increasing the strength, endurance of the patient and pliability of the spine, machines on and in which the patient is placed are then used for decreasing the rotation and curve. These machines enable the surgeon not only to get the most effective correction without overtaxing the endurance of the patient, but adapts the patient gradually to the pressure, which later on it may be necessary to apply constantly. A corrective day and night apparatus is used, followed in two to four months by corrective apparatus made from a cast representing the maximum amount of correction the patient will stand, applied with

FIG. 5.

head traction and side and rotary pressure by means of apparatus. The patient may be kept recumbent in the last appliance. Later the cast is remodelled and trial apparatus applied and altered as may be necessary. Such apparatus is changed to suit the condition every two to four weeks or six weeks, depending on the rigidity of the spine and the condition of the skin at the points of pressure.

There is not space to enumerate the small details of all the cases. The details of one or more difficult and elaborate cases may be of interest to illustrate what has been done in many of those cases included in the following table, although the exact outline has been different in each case.

Fig. 5 before treatment. Heavy muscular man with rigid curve and rotation.

Figs. 6 and 7 represent about nine months of actual treatment in a period of eighteen months. This correction of a rigid curve and rotation in a strong muscular man shows what may be done in eighteen months.

Fig. 6. Notice pressure mark and disappearance of rotation at point of arrow.

Fig. 7. Notice pressure mark and disappearance of rotation at point of arrow.

This patient, a girl of fourteen years of age, came to the office seven years ago with a cervical curve to the left, a long dorsal curve to the right, a short lumbar to the left with marked rotation and extreme rigidity, the body weight so displaced to the right that the patient could not stand without apparatus, and then the weight-bearing was only on one leg. The spine practically ankylosed in three acute angles. The rotation and curve was so great in the dorsal region that the erector spinæ muscle had slipped over the spinous process from the right to the left side. Length of the legs were the same. The position of the bony points of the pelvis almost symmetrical. This patient when a small child had scoliosis. The treatment was not understood where she lived and many years were wasted. The deformity rapidly increased until she was fourteen years old, when, as she presented herself to the writer, the condition as above was present. She was not at all strong and could stand very little treatment at a time, and was very sensitive to pressure. She was treated about three months at a time, three times a year. Her muscles developed and her general health greatly improved, and the curvature straightened a little. In addition to the bad scoliosis, she

Fig. 8. Extreme case in course of treatment.

could not when standing carry the weight on the left leg. By means of her arms and a hitching gait she was able to keep her balance in an upright position with the aid of apparatus. At first the weight of the middle section of the body was worked on regardless of the whole scoliosis, and the weight of this section displaced until it almost reached the middle line. When this was accomplished the patient was able to stand long enough to get a photograph (see Fig. 8). This picture represents the patient after two years of treatment. The case was very stiff and hard to work over. Many intermediate

FIG. 9. Same case.

photographs and details are here omitted. Fig. 10 represents the position two years after Fig. 8. Notice the ease in standing, though there is more deformity than appears in the photograph. Fig. 11 represents the condition two years later. Notice the good position, very great improvement in rotation. With clothes on, the patient appears straight. She is here about twenty-one years old. Without treatment she would have been a bedridden cripple. Now she is able to be extremely active and has more health and strength than the average well woman of the same age.

It is difficult to tabulate scoliotic cases, as many individual differences and the small details must necessarily be left out from the table. All these cases are more or less rigid in their curve or rotation. They have all passed the stage of the simple curve and have structural changes with rotation and rigidity.

To facilitate an analysis, the cases are classed according to the severity of the curve, all things being considered, into Groups 1, 2 and 3. As the cases are all severe, there will be in Group 1 the least severe; in Groups 2 and 3, those of increasing severity. To obviate mentioning elaborate details, the cases are subdivided into those in which the curve was not benefited, those that were improved, and then those that were greatly corrected.

With the intelligent use of the means of treatment, every case was benefited as to its general condition, muscular tone, strength and endurance. Such improvement, while beneficial to the patient, is not recorded in this report, where only the effect on the curve is considered.

Bearing these facts in mind, the patients are placed in the groups to which they belong before and after treatment. The length of treatment, the age, the varying rigidity of like curves, the curve itself must all be considered.

FIG. 10. Same case.

One hundred and eighty-two cases of advanced scoliosis with complicated structural curves were treated. Sixty-five, or one third, were greatly corrected, 97 were improved; 20 while benefited in strength, endurance and health, their curves were not improved.

Considering the degree of rigidity as a factor in those that were greatly corrected, 39 were of

slight degree of rigidity, none were extremely rigid.

Of the cases that were markedly improved, 32 were slightly rigid, 28 were rigid and 13 were extremely rigid.

Of the cases that were improved, 3 were slightly rigid, 11 were more rigid and 8 were extremely rigid.

Fig. 11. Same case.

Considering the age as a factor: of those that were greatly corrected, 17 were under twelve, 28 were from thirteen to eighteen, 13 were from nineteen to twenty-five, 6 were from twenty-six to thirty-five, and 1 was from thirty-six to forty. Those that were markedly improved, 7 were under twelve, 38 were from thirteen to eighteen, 24 were from nineteen to twenty-five, 3 were from twenty-six to thirty-five and 1 was from thirty-six to forty. Those that were improved, 5 were under twelve, 9 were from thirteen to eighteen, 6 were from nineteen to twenty-five, and 3 were from twenty-six to thirty-five, and 1 was from thirty-six to forty. Those that were not improved, 5 were under twelve, 7 were from thirteen to eighteen, 5 were from nineteen to twenty-five, and 3 were from twenty-six to thirty-five.

Considering the length of treatment: those cases that were greatly corrected, 8 were treated one year; 32 were treated two years; 22 were treated three years; 2 were treated four years; and 1 was treated six years. Those cases that were markedly improved, 18 were treated one year; 34 were treated two years; 14 were treated three years; 4 were treated four years; 1 was treated five years; 1 was treated six years; and 1 was treated seven years.

Those cases that were improved, 3 were treated one year; 16 were treated two years; 4 were treated three years, and 1 was treated six years. Those cases that were not improved, 10 were treated one year; 3 were treated two years (very irregular), 3 were treated three years

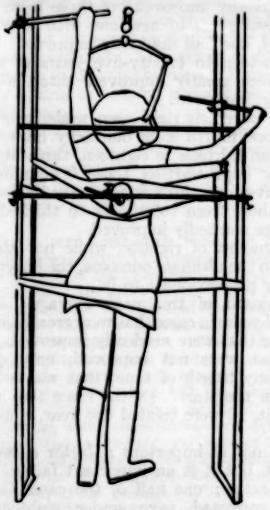

Fig. 12.

(very irregular), 1 was treated six years and 3, very irregular, less than one year.

Considering rigidity and age:

| | Total. | Greatly corrected. | Marked improvement. | Improvement. | No better. |
|---|---|---|---|---|---|
| **Slightly Rigid Cases.** | | | | | |
| Under 12 | 14 | 10 | 3 | 1 | 0 |
| 13–18 | 37 | 22 | 12 | 1 | 2 |
| 19–25 | 26 | 12 | 13 | 0 | 1 |
| 26–35 | 7 | 4 | 3 | 0 | 0 |
| 36–40 | 3 | 1 | 1 | 1 | 0 |
| **More Rigid.** | | | | | |
| Under 12 | 16 | 7 | 3 | 2 | 4 |
| 13–18 | 29 | 6 | 16 | 5 | 2 |
| 19–25 | 14 | 9 | 9 | 3 | 1 |
| 26–35 | 4 | 2 | 0 | 1 | 1 |
| 36–40 | 0 | 0 | 0 | 0 | 0 |
| **Very Rigid Cases.** | | | | | |
| Under 12 | 4 | 0 | 1 | 2 | 1 |
| 13–18 | 15 | 0 | 9 | 3 | 3 |
| 19–25 | 10 | 0 | 3 | 4 | 3 |
| 26–35 | 3 | 0 | 0 | 1 | 2 |
| 36–40 | 0 | 0 | 0 | 0 | 0 |

Considering the age and classing the cases according to rigidity: Of slightly rigid cases, under twelve years of age, two thirds were greatly

improved; of those from thirteen to eighteen years of age, almost two thirds were straightened, one third markedly improved; of those from nineteen to twenty-five, almost one half were straightened, one half were markedly improved; of those from twenty-six to thirty-five, over one half were straightened, one half were markedly improved. In other words, much may be expected with much deformity at all ages where there is a low degree of rigidity.

Of the more rigid cases, under twelve years of age, one half were greatly improved, one fifth were markedly improved; of those from thirteen to eighteen years of age, one fifth were greatly improved, one half markedly improved; of those from nineteen to twenty-five years of age, one fourth were greatly improved, three fifths were markedly improved.

Of the extremely rigid cases, under twelve years of age, one fourth were markedly improved; of those from thirteen to eighteen, three fifths were markedly improved; of those from nineteen to twenty-five, one third were markedly improved, and of those from twenty-six to thirty-five, one third were markedly improved.

The amount of rigidity, while not absolutely a guide to the ultimate outcome, the improvement is largely proportionate to it.

The length of treatment averaged two and one-third years in cases that were greatly improved and cases that were markedly improved. Of the cases that were not improved, only one was treated any length of time; that was a hopeless case from the start. Of the cases that received no benefit, 10 were treated one year, 9 were very irregular.

Age is not as important a factor as would be supposed, but it is an important factor, as may be seen below; one half of the cases that were greatly corrected were under eighteen; one third were over twenty-five. Cases that were markedly improved, over one half were under eighteen, one third were over twenty-five.

The general health, muscular condition and endurance is greatly benefited in all cases. To make an impression on the curve, length and perseverence in treatment is more of a factor than age, but the amount of rigidity of the curve is more important than the amount of curve. Age is a factor, but two thirds of those over twenty-five were greatly corrected or greatly benefited. Almost all cases may be improved; some greatly improved and severe cases with moderate rigidity may be greatly corrected.

While in these stiff and extremely deformed cases the treatment requires a good deal more time than for simple curves, and for some cases there is a sacrifice of personal comfort for a short period, still the fact remains that it is effective treatment and one of the easiest, and for the patient a most comfortable way to correct difficult rigid structural scoliosis in a comparatively short time. The future of the patient, the health, and to prevent a crippled or semi-invalid condition makes it necessary not to trifle in the treatment of advanced cases of scoliosis. The slight curves may be treated with much less sacrifice of time and less strenuous work, depending on the severity of the case. Difficult cases of scoliosis, with complicated curves, rotation and rigidity form a class which are often very discouraging to treat. The writer wishes to make a plea for very rigorous treatment in these cases, for not only may they be vastly improved, but treatment can in most cases prevent them from being badly deformed or crippled later on.

## ACUTE DILATATION OF THE STOMACH FOLLOWING SURGICAL OPERATIONS.*

BY EDWARD WALLACE LEE, M.D., NEW YORK.

THIS is an infrequent complication, but one of the most serious that may follow any surgical procedure. It is more liable to follow operations in the abdominal or pelvic cavities. Laymen frequently facetiously remark: "Doctor, you may consider your operation successful, but your patient died." This remark is often true. The operation has been successful, but an unforeseen, unavoidable, and often fatal complication, especially of this character, brings about unjust and unfavorable criticism of the surgeon's work. My limited experience has demonstrated the seriousness of this complication, and the subject is presented to this Association more for discussion than for any definite information the writer may have to impart.

It is fitting that this subject should be discussed before a society of this character, made up, as it is, of general practitioners and the exponents of many of the different so-called specialties in medicine. Frequently the surgeon after operation leaves his patient under the care of the family doctor, and, therefore, the latter must assume the responsibility of the after-treatment. He should be well prepared to recognize the various complications which may arise, and as this is one of the most serious, it ought not to be overlooked. As has been stated, it is especially liable to follow operations in the abdominal or pelvic cavities. We often see after abdominal section various gastric and intestinal disturbances which greatly complicate and retard recovery, and the early recognition of these may sometimes prevent a fatal termination.

### ETIOLOGY.

My own observations have not been such as to enable me to assign a cause that would directly produce this condition. There are many theories as to its cause,—the anesthetic, extent of operation, its location, all have been given as possible causes, but experience so far has shown that this sequela may follow various surgical procedures, regardless of the anesthetic, location, extent or character of the operation. Various other causes have been mentioned, such as spasm of the pylorus, volvulus of the stomach, kink in the duodenum, and pressure on the mesenteric vessels (irritation of the solar plexus, after removal of large uterine fibroid tumors, permitting of general ptosis of the

* Presented at the meeting of the Medical Association of the Greater City of New York, Feb. 20, 1911.

abdominal contents, which press down on the mesenteric vessels, thereby interfering with proper circulation and nerve function). But it is not to mechanical causes that I especially refer, for of course if *existing*, they are self *evident*.

It is a question whether this condition is due to a neurosis producing paralysis permitting the formation of gases, which would naturally be followed by gastric dilatation, or to an irritation continuously producing excessive gastric secretion. From my observation I am inclined to look upon it as due to a neurosis, some serious vasomotor nerve disturbance, rather than to any direct irritation of the stomach itself. Even after the stomach has been thoroughly irrigated, having been emptied of its contents, it will rapidly refill with secretion and become enormously distended with gas, and on post-mortem examination it has been found that the dilated stomach was free from contents with the exception of gas.

### DIAGNOSIS AND CHARACTERISTICS.

There are certain signs and symptoms of acute gastric dilatation which may be considered pathognomonic. On physical examination we find the stomach dilated sometimes to its normal capacity, but often extending into the pelvis. The condition is diagnosed by inspection and palpation, and the various lines of symptoms which accompany it. It usually comes on anywhere from one hour to twelve to fourteen hours after the operation. In one case I observed it within an hour after the patient had been placed in bed. The earlier symptoms are apparently those of shock, and when I say shock, I mean that extreme shock in which intolerable vomiting occurs. The contents of the stomach are followed by expulsions of glairy mucus, and, if the vomiting continues, of mucus streaked with blood. Often the vomitus is brought up in large gulps without straining. Aside from the vomiting, the surgeon's attention should be attracted by the rapid and constantly increasing pulse. The symptoms are often allied to those of internal hemorrhage, but this complication can usually be excluded by taking into consideration all the details of the operation.

The general condition of the patient is recognized as being serious from the first. The respirations are frequent and shallow, the pulse rapid, thready and of poor quality, and the skin often cold and clammy. The aspect of the patient indicates that his tissues are deficient in water; he is pinched and careworn, and appears to have aged suddenly. He is apt to be restless, and at times irritable. Diarrhea has been observed, and the urine is nearly always scanty. On palpation and inspection the stomach is usually found enormously distended and sharply bent upon itself, so as to form a gigantic "U." Generally on the lesser curvature there is a sharp kink. The stomach occupies the greater part of the abdominal cavity, cutting off the large and small intestines. Of course, the stomach walls are tightly stretched and consequently thin.

From an anatomical point of view there is a characteristic condition which is self-evident. That the stomach is enormously distended can be easily recognized, especially in thin patients, by the distention extending toward the left side; even causing bulging of the ribs as it forces itself up under these and presses on the diaphragm, thereby causing mechanical interference with the heart's action. This mechanical interference, combined with the general systemic shock, brings about a condition which it can be readily understood is likely to prove fatal. I emphasize the distention toward the left because on the right side of the upper abdominal region there is flatness on percussion, the abdominal wall at times being retracted and allowing the liver to be easily palpated. This point is worthy of special attention, as it is the means, if recognized, of greatly aiding in making a diagnosis of acute gastric dilatation.

I have seen a number of these cases, but will report but four or five. The cases observed have been males (between the ages of forty-three and seventy) with one exception, and this exception will be referred to later on.

Case I. A man forty-three years old had been operated for appendicitis. Two years later he developed hernia on the side of the operation. He was operated on for the hernia. He was a strong, robust man, with apparently no gastric or intestinal disturbances, but, being an army officer, it became necessary that his hernia should be operated on. Within four hours after the operation there was an enormous distention of the stomach — gastric, not intestinal, dilatation. The line of treatment which will be described was followed out. This case made a recovery.

The following three cases terminated fatally.

Case II. Man, sixty-five; gall-bladder case; removal of large single stone and the gall bladder. Within eight hours after the operation there developed an acute dilatation of the stomach. The general line of treatment was followed out, but death ensued thirty-six hours after the operation.

Case III. Suprapubic prostatectomy; a man sixty years old. Acute dilatation of the stomach followed within fourteen hours after the operation. In this case the patient was a cocaine habitué of highly nervous temperament and physically in bad condition. What these elements had to do with bringing about the acute dilatation and fatal termination are questions for your consideration.

Case IV. Suprapubic cystotomy for chronic purulent cystitis. Within one hour after the operation acute dilatation of the stomach with all its characteristic and distressing symptoms was apparent. Every form of treatment indicated was carried out. Fatal termination forty-eight hours after the operation.

As I have said, the cases I have observed have been males with one exception. This was a woman twenty-six years old, and the case does not, strictly speaking, belong to this category, as the acute dilatation did not follow surgical operation, but a burn. The latter was of the second degree, in extent about six inches square, and situated on the upper abdomen. The burn in itself was not serious enough to have produced the symptoms which followed within three hours after the injury, but within that period there was acute dilatation

of the stomach with all its characteristic symptoms. The case terminated fatally twelve hours after the injury. I refer to this case as tending to carry out the idea that acute dilatation of the stomach is of nervous origin rather than due to actual mechanical irritation of the stomach itself.

TREATMENT.

As has been stated, we find the patient in profound shock and the stomach enormously distended, not only with secretion, its so-called normal contents, but gas. The indication is to resort as soon as possible to remedies which will relieve shock and sustain the patient. Mechanical irrigation, washing out of the stomach, is *primarily* indicated. The stomach should be relieved of its other contents and gas by the introduction of the stomach tube, and if necessary the tube should be left in until there is no further indication for its use. In some cases it has been observed that even after thorough evacuation of the stomach contents, and the liberation of the existing gas, the stomach will rapidly refill not only with secretion, but with gas; therefore in many instances the permanent use of the tube is indicated.

The drugs indicated are, first, morphine, to relieve pain and shock, and next, strychnine, to stimulate the heart's action. This is given also for its effect on the vasomotor nervous system, with the hope that it may induce contraction of the distended stomach, for we know that strychnine is a powerful contractor, if I may use the term, stimulating the contraction of the involuntary muscles. We know that it is of service in acute dilatation of the heart, and we know that it is one of the most reliable remedies in post-partum uterine dilatation. Another remedy in use is eserine, which is indicated on account of its efficiency in bringing about peristalsis. This drug is strongly advised if there is any evidence that the colon or the small intestines are implicated in the existing distention.

Various surgical procedures have been recommended, *none* of which I have ever resorted to, for in the first place, the shock is so severe that any operation would necessarily increase the amount of existing shock. Gastrostomy and gastro-enterostomy have been suggested. The latter, I believe, is too complicated a procedure to be even thought of. Gastrostomy could be resorted to under local anesthesia, and I believe that it has certain indications which are at least theoretically logical.

The general line of treatment resorted to after all surgical procedures should, of course, be carried out to bring about if possible a favorable termination, though this condition is of so serious a character that a majority of the cases (75%) terminate fatally. So grave an affection should receive our most earnest consideration, and this, therefore, is the principal reason why the subject has been presented to you. The general literature and general discussion of this subject have been too limited for a condition so serious and important.

## ACUTE POST-OPERATIVE DILATATION OF THE STOMACH.*

BY ROBERT T. MORRIS, M.D.,

*Professor of Surgery at the New York Post-Graduate Medical School and Hospital.*

WHEN an artist cannot draw very well, he turns to making impressionist views, and that is the sort of picture I would draw of this condition. Acute post-operative dilatation of the stomach presents four salient features: (1) The initial disturbance; (2) increased peristalsis and antiperistalsis; (3) great dilatation of the stomach walls; (4) extreme amount of secretion.

We can group a number of features in the perspective.

(*a*) Hormones secreted in the stomach mucosa stimulate activity of secretory glands.

(*b*) Chromaffin secretions from ductless glands and sympathetic ganglia control motor activity in part, and conduct trophic influence in part.

(*c*) The cerebrospinal nerves conduct motor activity.

Shock, ether and toxins are all known to derange the action of chromaffin secretions, and that could account for the deranged action of the sympathetic nerves in these cases. Shock, ether and toxins may overstimulate the sympathetic nerves. Overstimulation of the inhibitory nerves of the stomach would have about the same result as cutting the vagus, which we know experimentally leads to enormous dilatation of the stomach. The stomach, like the heart, has a systole and diastole. So much for the dilatation part of the picture.

Shock, ether and toxins may all derange the action of the hormones, with consequent loss of control of the secretory glands, which would then give us some products in excessive proportion, and other products in diminished proportion. So much for the vast quantities of fluid in the stomach in these cases, and for the gas, when saprophytes take charge of material given over to them by deranged digestion controllers.

Shock, ether and toxins may all disturb the cerebrospinal system, but we may assume that this later development of the embryo is more resistant and less easily influenced than the primitive sympathetic system. This idea places the cerebrospinal system practically out of our picture.

Now let us get theories into concentrated space, and use Dr. Lee's case of burn of the abdomen for a bull's-eye. Let us think at a target, and see if we can hit that bull's-eye. It was a small burn of the upper abdomen, yet the patient had acute dilatation of the stomach and died in two days. How could a small superficial burn do all that?

Heat transforms some albuminous tissue into

* Presented at the meeting of the Medical Association of the Greater City of New York, Feb. 20, 1911.

At the meeting of the Medical Association of the Greater City of New York, on Feb. 20, Dr. Edward Wallace Lee read a paper on the subject of "Acute Dilatation of the Stomach (JOURNAL, page 562). He reported upon cases of his own, and among these was a case following a small burn of the abdomen. Our regular correspondent, who was present, has suggested that we publish the discussion of Dr. Morris in full, and as an original contribution.

toxalbumin. The toxalbumin overstimulated the inhibitory nerves of the stomach until they overcame the influence of the vagus. That gave the dilatation in the case. The toxalbumin intoxicated the chromaffins until their influence overexcited the peaceful hormones, and we had a crazy lot of products filling the stomach. The patient could not stand the effect of intoxicated malefactors snarling up his sympathetic nerves, and he died exhausted.

We need not talk about spasm of the pylorus, or angulation of the duodenum as adding to the patient's misery, because that would lead us to think to the left of our bull's-eye. We need not talk about differences in action between shock, ether and various kinds of toxins, because that would lead us to think to the right of the bull's-eye.

We need not talk about gastric dilatation of chronic form and unknown origin, because that would lead us to think over the bull's-eye.

We need not talk about cases of bowel dilatation associated with gastric dilatation, because that would lead us to think under the bull's-eye. Let us think straight at the target of the little burn case, and make at least one score in our subject.

What are we to do for our cases of acute gastric dilatation? Place the patient upon the abdomen, inclined a little to the right side. That will mechanically compress the dilated stomach and unkink the duodenum.

Wash out the stomach every hour or two if necessary with the stomach tube. That allows the postural mechanical resource to become more effective, and it takes away saprophyte poisons.

Many of these patients will progress steadily toward recovery from the very moment of application of these two simple resources.

## AN ANALYSIS OF FORTY-SIX CASES OF PROSTATECTOMY.

BY LINCOLN DAVIS, M.D., BOSTON.

(Continued from No. 15, p. 524.)

### CANCER OF THE PROSTATE.

THERE were nine cases of cancer of the prostate operated upon without mortality, three by the suprapubic route. In one case the entire gland with seminal vesicles was dug out en masse. The wound healed and the patient left the hospital greatly relieved only to die of the disease within six months. In the other cases the prostate was partly dug out, or burned through, relieving the obstruction, but without attempt at radical removal of all the disease. The wounds healed and the patients left the hospital relieved. Both have been heard from recently through their physicians, more than three years after operation. In one case there has been a return of obstruction, necessitating the use of the catheter, but the general condition of the patient remains excellent. In the other case, his physician states that the patient's health is certainly as good as before he was troubled with his prostate. Outside of some frequency, his bladder condition is good. In the latter case, the final pathological report on the specimen removed is missing, so that the diagnosis of cancer which was made by the rapid method during operation is open to doubt. In the other case, the pathological report is malignant adenoma; in view of the subsequent history, a secondary operation preferably by the perineal route is indicated, in my opinion.

Six cases of cancer were operated on through the perineum. In none of these was a radical removal attempted. Five patients left the hospital with obstruction relieved and good control. Four of these have died of the disease within a year of operation. One is living and comfortable nine months after operation. One patient had incontinence and a persistent perineal fistula after operation. He died of the disease within a year. In one case in which the gland was very adherent to the rectum, a tear was made in that viscus. This was the only time this complication has occurred in my series. An attempt was made to close it at the time, also two subsequent attempts, all failed. Finally, the rectal wall including the sphincter was split up to the fistula, and allowed to granulate. He had incontinence of both urine and feces for about two months, but later acquired control of both rectum and bladder, although the urine continued to be passed through the perineum. He has survived the operation for a year and is able to be up and about, but is slowly failing.

I have acquired a wholesome dread of operating for cancer of the prostate. My present feeling in regard to the matter is, in early cases the conservative perineal operation with removal of the median bridge is well worth while, often giving months or years of comfort with the possibility of a cure. In advanced cases operate only when you must to relieve obstruction. The radical perineal operation of Young does not appeal to me.

### TUBERCULOSIS OF THE PROSTATE.

My experience with prostatectomy for tuberculosis is limited to one case operated under the mistaken diagnosis of cancer; it was unfortunate in the extreme; the symptoms were retention and bleeding with a stony prostate. I operated by the Proust method. The wound never healed, the bladder was diseased and contracted, holding only 1 oz. The patient left the hospital wearing a perineal tube, without control of the bladder, and died of the disease four months later.

I am convinced that tuberculosis of the prostate is rarely if ever amenable to surgical treatment, the disease is practically never limited to that organ alone, and the best results will be obtained by general medical anti-tubercular treatment

### ABSTRACTS OF CASES.

#### PERINEAL PROSTATECTOMY FOR BENIGN ENLARGEMENT.

CASE 10. J. R., No. 158291. E. S. Age, sixty-seven years. Married. Machinist. Entered the hospital May 7, 1908. Service of Dr. Scudder.

*History.* — No venereal diseases. Six years ago began to have difficulty with micturition. Urine did not come freely. Occasionally had to use catheter. Fourteen weeks ago complete retention, physicians unable to catheterize. Suprapubic puncture, and later perineal section done at an out-of-town hospital. Since then has had to use the catheter at frequent intervals.

*Examination.* — Fairly developed and nourished. By rectum prostate greatly enlarged, hard and smooth. Healed scar in perineum. Double inguinal hernia.

*Urine*, high, alkaline, 1015, albumin slight trace, sediment, many pus cells, few blood corpuscles, triple phosphate crystals.

*Cystoscopic examination.* — No note. Patient put on constant drainage.

*Operation*, May 12, 1908, preliminary suprapubic cystotomy with removal of soft stone by Dr. Scudder.

May 25, 1908, perineal prostatectomy. L. D. Two medium-sized lateral lobes and one median lobe removed, double tube drainage and gauze packs to lateral cavities.

*Pathological report.* — Diffuse hypertrophy.

*Convalescence.* — Pulse poor, considerable staining, wound repacked. Tubes and packing out in twenty-four hours. June 1, right epididymitis. June 5, suprapubic wound closed. June 10, no leakage through perineum, good control. June 18, discharged on twenty-fourth day, perineal wound nearly closed, no leakage, no residual.

*Subsequent history.* — June 22, 1909, examined. Patient feels finely and is at work. Control of bladder not good, wears urinal for comfort. Can hold urine about one-half hour, then it is apt to dribble a little. Bougie catheter passed, residual 1 oz., urine slightly turbid. Wound healed.

CASE 12. T. E. W., No. 159929. E. S. Age, sixty-two years. Married. Mason. Entered the hospital Aug. 24, 1908. Service of Dr. Brooks. Recommended from Out-Patient Department. Diagnosis, prostatic obstruction (difficult to catheterize) urgent.

*History.* — No serious illnesses. For last dozen years has had trouble in passing water. At first difficulty in starting stream, then less and less force. Dull pain over the pubes, and ardor urinæ. Has used a catheter off and on for two years. Cannot use catheter now on account of pain. Three days ago had retention.

*Examination.* — Well developed, thin. By rectum prostate enlarged, moderately smooth, hard, somewhat tender. Catheter passed with some difficulty. Residual, 4 oz. foul urine. Right inguinal hernia.

*Urine.* — Aug. 26: Red, alkaline, 1012, albumin ¼%, sugar 0, sediment — blood and pus. Twenty-four-hour-amount, 1020 ccm.; urea, 1.23% — 12.5 gm.

*Cystoscopic examination.* — Bladder inflamed and bleeds easily, very little intravesical enlargement of prostate made out.

*Operation*, Sept. 1, 1908, perineal prostatectomy. L. D. Young's technic. Seepage, double tubes, and gauze packing.

*Pathological report.* — Chronic hypertrophy.

*Convalescence.* — Sept. 2, packing and tubes out. Sept. 4, small amount of urine passed through urethra. Sept. 21, discharged on twentieth day. Wound closed, interval urination.

*Subsequent history.* — Treated quite continuously since operation in Out-Patient Department for persistent colon cystitis, bladder washings, sounds, etc. October, 1909, can hold water all night, no dribbling, general health excellent. Both urines moderately turbid. Residual, 1½oz. Sounds 26–28 to bladder, wound healed. January, 1911, last note: Residual, 25 ccm. Residual has at times been as high as 4 oz.

CASE 14. J. Y., No. 160852. E. S. Age, fifty-eight years. Married. Printer. Entered the hospital Oct. 26, 1908. Service of Dr. Harrington.

*History.* — Denies venereal. During last two or three years has had gradually increasing difficulty in starting stream, frequency especially at night (four times). During past year symptoms have increased in severity. Five days ago retention and again two days ago, since then catheterization.

*Examination.* — Well developed and nourished. Systolic murmur. By rectum, moderate enlargement of lateral lobes.

*Urine* turbid, alkaline, specific gravity 1010, albumin ¼%. Many blood corpuscles and leucocytes.

*Cystoscopic examination* in Out-Patient Department. Hypertrophied and bleeding third lobe seen.

*Operation*, Oct. 29, 1908, perineal prostatectomy. L. D. Usual technic. Third lobe, size of horse chestnut, pulled down through prostatic urethra and cut off. Usual drainage and seepage.

*Pathological report.* — Six small lobular glandular masses. Diagnosis, hypertrophy.

*Convalescence.* — Oct. 30, tubes and packing out. Nov. 1, has interval urination through wound, passing a little urine through penis. Nov. 16, slight epididymitis. Nov. 19, 1908, discharged on twenty-first day. Epididymitis subsided, perineal wound nearly healed, occasional slight leakage from it.

*Subsequent history.* — Nov. 29, 1909, examination in Accident Room. Feels and looks perfectly well. No trouble with water. Occasionally gets up once at night to urinate. Works hard. No symptoms. Residual measured in Out-Patient Department, 1 dr. Wound healed.

CASE 15. G. M., No. 162431. S. S. Age, sixty-eight years. Married. Silversmith. Entered the hospital Feb. 13, 1909. Service of Dr. Mumford.

*History.* — Denies venereal. For past year has had to urinate at night two to four times. Within a month has had some difficulty in starting stream, some dribbling. Yesterday had retention. Relieved by catheterization.

*Examination.* — Rather feeble and tremulous. Systolic murmur. By rectum, prostate large, firm, smooth, not tender, soft rubber catheter passed and tied in. Patient noisy at night.

*Urine*, acid, 1020, albumin trace, sediment — pus and blood and squamous cells. Quantity varied from 25–50 oz.

*Cystoscopic examination.* — Marked intravesical enlargement of prostate, especially on right. Contour is smooth, some bleeding.

*Operation*, Feb. 23, 1909, perineal prostatectomy. In removing left lobe prostatic urethra torn into. Third lobe removed. Urethra sutured. Gauze packing. Double tube drainage and seepage, subpectoral infusion.

*Pathological report.* — Prostatic tissue weighed 70 gm. Some tendency to proliferation of epithelium.

*Convalescence.* — Gauze and tubes out in twenty-four hours. Patient unable to void. Single perineal tube inserted. Wound infected. March 1, put on urethral catheter drainage. March 12, abscess of testicle incised with evacuation of pus. March 30, passing urine through urethra for first time. April 17, passing urine naturally. Discharged seventy-third day. Wound closed.

*Subsequent history.* — Treated several times in the Out-Patient Department. Last note, July 21, 1909, nocturia 1–2. No frequency by day. No pain except slight smarting at head of penis on starting stream. Residual, 2 oz.; lowest residual recorded was 1 oz. Wound is healed. Has gained considerably in strength but is unable to work. Perfect control of bladder.

Case 16. A. B., No. 162 803. S. S. Age, forty-seven years. Married. Fish pedler. Entered the hospital March 9, 1909. Service of Dr. Mumford.

*History.* — Denies venereal. Since last autumn steadily increasing difficulty in voiding, with increasing frequency. Constant dribbling for last month. Residual of 25 oz. found in the Out-Patient Department.

*Examination.* — Well developed and nourished Hebrew. General condition excellent. Knee-jerks present. No evidence of spinal cord disease. By rectum, prostate large, smooth and tender. Soft rubber catheter passed without difficulty and bladder, which reached almost to umbilicus, emptied of a large amount of clear pale urine. Patient put on constant drainage.

*Urine.* —Amount varied from 48–145 oz. before operation. Pale, acid, 1005, albumen 0.

*Cystoscopic examination.* — Report missing.

*Operation*, March 12, 1909, perineal prostatectomy. Lateral lobes shelled out, found much smaller than expected. A small portion of a median lobe was left. Prostatic urethra torn, sutured. Usual drainage.

*Pathological report.* — Fibrous and glandular hypertrophy.

*Convalescence.* — General bronchitis following operation. After removal of perineal tube patient had partial retention and catheter was tied in through urethra. April 5, 1909, discharged on twenty-fourth day, patient passing urine naturally, wound almost closed.

*Subsequent history.* — May 10, 1909, Out-Patient Department notes: Wound healed, urine clear, residual less than ½ oz., rises once at night, no urinary symptoms. Nov. 2, 1909: No urinary symptoms whatever. Comes in for treatment of bronchitis.

Case 17. W. M. R., No. 162887. W. S. Age, seventy-nine years. Married. Manufacturer. Entered the hospital March 14, 1909. Service of Dr. Mixter.

*History.* — In good health until last year. Had abscess of testicle. Testicle removed by operation. Wound has not closed. Had an operation for inguinal hernia shortly before this. For two years has had difficulty and frequency of micturition. Lately has had to be catheterized, which is very painful; desires an operation to be relieved of catheterization.

*Examination.* — Well developed and nourished old man. Left testicle missing, discharging sinus in groin. By rectum prostate enlarged, slightly irregular, firm and tender.

*Urine*, normal color, acid, 1015, albumen slight trace. Sediment — numerous pus cells, squamous cells and bacteria.

*Cystoscopic examination* not attempted on account of pain caused by simple catheterization.

*Operation*, March 15, 1909, perineal prostatectomy. Gland tough and fibrous, enucleated with difficulty. Prostatic urethra torn. Very little bleeding. Usual drainage.

*Pathological report.* — Fragmentary masses together size of small potato. Glandular hypertrophy with purulent inflammation.

*Convalescence.* — March 18, all wicks out, good condition. March 21, sutures out, wound granulating, urine comes through wound. March 26, patient has control, sitting in chair. Condition excellent. Pulse, 80. Temperature, normal. Wound clean. March 28, temperature up. Facial erysipelas. The erysipelas spread to the neck and chest, temperature and respirations remained elevated. Patient became irrational and wandering. April 3, erysipelas better. Pneumonia of right lung developed. Patient failed rapidly and died April 4, on the twentieth day. No autopsy.

Case 19. J. F. A., No. 163867. W. S. Age, fifty-six years. Married. Lawyer. Entered the hospital May 10, 1909. Service of Dr. Mixter.

*History.* — Gonorrhea several times. Has been a heavy drinker in the past. For two years has had difficulty with urination. About one and one-half years ago began the use of a catheter at night. For last six months has used it two or more times a day. Residual, about 12 oz. Last two days has had great difficulty in passing the catheter and has to use it frequently.

*Examination.* — Well developed and nourished, pasty appearance, heart and lungs sound. By rectum, prostate hard, symmetrically enlarged, not tender. Coudé catheter passed in office and 8 oz. cloudy urine withdrawn.

*Urine.* — Acid, 1020, albumen 0, sugar 0.

*Cystoscopic examination.* — No note.

*Operation*, May 13, 1909, perineal prostatectomy. Two moderate sized lateral lobes, small third lobe shelled out through left lateral cavity. Pus in prostate. Usual drainage.

*Pathological report.* — Fragmentary masses of prostate showing glandular hypertrophy with retention cysts.

*Convalescence.* — May 14, packing removed, followed by severe hemorrhage. Wound repacked. Seepage continued. Patient blanched and exhausted. Pulse rose twenty beats. May 16, wicks removed, no bleeding, tubes out. May 18, no control. May 26, first urine passed through urethra. May 31, voids 5–6 oz. at a time with control. June 5, discharged twenty-third day. Wound granulating.

*Subsequent history.* — Epididymitis after discharge from hospital, sounds passed at intervals and bladder irrigated. Oct. 15, 1910, last seen. General health excellent. No urinary symptoms except rises once or twice at night. Perfect control, holds water three to four hours during day. Good stream. Wound healed. Residual less than 1 oz. Urine acid, turbid, contains colon bacilli and small amount of pus. Only complaint is loss of sexual power. Very slight power of erection.

Case 20. J. S., No. 164024. E. S. Age, seventy-three years. Married. Gardener. Entered the hospital May 20, 1909. Service of Dr. Scudder and Dr. Brooks.

*History.* — Gonorrhea in early youth. For two years has had pain and frequency of urination. Never used catheter. Early this morning patient unable to void, considerable pain. Local physician unable to catheterize. Patient brought to Accident Room.

*Examination.* — Well developed and nourished old man. Râles in bases of both lungs. Bladder distended to the umbilicus. Catheterization impossible on account of tight stricture in membranous urethra. Some bleeding. By rectum prostate felt considerably enlarged and hard.

*Operation*, May 20, 1909, perineal section with division of tight stricture of deep urethra. Dr. Scudder. Patient had pain and tenesmus and inability to pass urine after removal of catheter.

*Urine*, cloudy, acid, 1020, albumen trace, much blood.

*Cystoscopic examination.* — Through perineal wound showed marked projection of third lobe. Prostatectomy advised.

*Operation*, June 9, 1909, perineal prostatectomy. L. D. Prostate contained pus, very adherent. Lateral and median lobes removed with considerable difficulty.

*Pathological report* missing.

*Convalescence.* — Usual post-operative treatment. After removal of perineal tube on third day patient

unable to void, catheter passed through perineum. June 18, patient urinates through wound with partial control. June 22, 1909, discharged thirteenth day. Patient insists on going home. Good control but nearly all urine passes through perineal wound.

*Subsequent history.* — June 27, 1910, returns for re-examination. Perfect control. Only occasionally has to get up at night. No pain, feels fine, wound healed.

CASE 21. P. S., No. 164225. E. S. Age, sixty-two years. Widower. Gardener. Entered hospital June 3, 1909. Service of Dr. Brooks.

*History.* — Denies venereal. For four or five years has had difficulty with micturition. Two years ago retention, twice since, relieved by catheterization. Has been under treatment in Out-Patient Department for two months. Bladder irrigation, etc. Residual urine varied in amount from ¾ to 4 oz.

*Examination.* — Well-preserved man. Heart and lungs normal. By rectum, prostate moderately enlarged, especially on left.

*Urine*, cloudy, acid, 1028, albumen 0, sugar 0; urea 2.02%.

*Cystoscopic examination* in Out-Patient Department showed moderate intravesical enlargement of prostate with small median lobe which bleeds. Bladder only holds 3 oz.

*Operation*, June 5, 1909, perineal prostatectomy. Small lateral lobes. Usual drainage.

*Pathological report* missing.

*Convalescence.* — Good recovery. Tubes out in forty-eight hours. June 11, up in chair, comfortable. Partial control. June 21, discharged to Out-Patient Department, sixteenth day. Interval urination with good control. Some leakage through perineal wound. Residual, 1 oz.

*Subsequent history.* — June 26, 1909, Out-Patient Department note: Slight leakage from wound. Rises once at night. Residual, ½ oz. March 17, 1910, rises once at night. Holds urine three or four hours during day, perfect control. No urgency. Wound solid. Urine clear. General health excellent. June 23, 1910, general condition excellent, gained 15–20 lb. in weight. Perfect control. Urine clear.

CASE 22. P. F., No. 164255. E. S. Age, seventy-eight years. Widower. Shoemaker. Entered the hospital June 5, 1909. Service of Dr. Brooks.

*History.* — Sent in from Out-Patient Department with diagnosis, retention of urine and cystitis from prostatic obstruction. Has been in poor health for years. Chronic bronchitis. For ten years has had difficulty with micturition. Catheterization occasionally resorted to for last two years, daily for last five months. For last two weeks much pain and straining with dribbling, unable to pass catheter himself, has been catherized by a physician. Bladder distended, 18 oz. withdrawn by catheter in Out-Patient Department.

*Examination.* — Thin, wasted old man. Moist rales in chest. By rectum, prostate moderately enlarged, firm, not nodular. Put on constant urethral drainage.

*Urine*, cloudy, acid, 1012, albumen slight trace, urea 1.64%, 9.50 gm. in twenty-four hours. Sediment — blood and pus.

*Cystoscopic examination* not made.

Patient considered poor risk, operation undertaken at earnest solicitation of patient.

*Operation*, June 19, 1909, perineal prostatectomy. Lateral lobes shelled out almost entire. Prostatic urethra uninjured. No third lobe. Usual drainage.

*Pathological report* missing.

*Convalescence.* — Tubes and packing out in forty-eight hours. June 24, sitting in chair. July 6, interval urination through penis. July 16, urine voided naturally during day, some leakage at night. Perineal wound almost healed. Urine quite clear, residual ½ oz. Discharged to local doctor twenty-seventh day.

*Subsequent history.* — Letter of Aug. 24, 1909, reports that he passes urine naturally and without pain for the first time in five years. He reports the operation a marked success. His local physician reported verbally six months later that the wound was healed and his condition excellent.

CASE 23. S. C., No. 164709. E. S. Age, seventy years. Single. Farmer. Entered hospital July 5, 1909. Service of Dr. Brooks.

*History.* — Never had a sick day. Denies venereal. For past four years has had increasing difficulty in passing urine. First attack of retention two years ago, since then it has recurred six times. Relieved by one or two catheterizations. Two days ago, retention; catheterized once by doctor who was unable to pass a catheter a second time. Brought to Accident Room.

*Examination.* — Well developed, fairly nourished. Considerable arteriosclerosis. Bladder distended almost to umbilicus. Catherization impossible, considerable bleeding. Immediate operation advised. Prostate by rectum felt large, soft, symmetrical.

*Operation*, July 5, 1909, perineal prostatectomy. Usual technic. Two lateral lobes shelled out, small median lobe. Usual drainage.

*Pathological report.* — Very adenomatous type of glandular hypertrophy.

*Convalescence.* — Wicks and tubes out in forty-eight hours. July 10, patient up in chair, urine comes through wound but with control. July 17, urine beginning to come through urethra. July 27, urine passed naturally with slight leakage through perineum. Urine clear. No residual. July 29, discharged, twenty-fourth day.

*Subsequent history.* — Aug. 30, 1910, patient readmitted for closure of small perineal sinus which leaks a few drops during micturition. Perfect control of bladder. Urine pale, neutral, 1010, albumen 0, sugar 0. General health excellent. Has been cultivating a small farm. Has had no medical treatment since discharge.

*Operation*, Aug. 31. Sinus curetted out under ether.

Letter, Dec. 24, 1910: Sinus has opened again and leaks a few drops almost every day. Feels well except for constipation. Passes urine three or four times a day but seldom at night. No pain. States that he has been able to do all his harvesting alone.

CASE 24. H. B., No. 165329. E. S. Age, sixty-five years. Married. Shoemaker. Entered hospital Aug. 12, 1909. Service of Dr. Brooks.

*History.* — Patient speaks very little English. Never any previous sickness. For three years difficulty with micturition with pain and frequency. Has been catheterized daily for last eight days. Urine foul.

*Examination.* — Poorly developed and nourished Hebrew. Arteries slightly roughened and thickened. Bladder distended to umbilicus. One quart of high-colored urine withdrawn. Knee-jerks normal. By rectum prostate smooth, symmetrical, moderately enlarged.

*Urine*, cloudy, acid, 1025, albumen trace, sediment — pus, few red cells, no casts.

*Cystoscopic examination.* — Unsatisfactory on account of bleeding.

*Operation*, Aug. 13, 1909, perineal prostatectomy. Usual technic. Two lateral lobes, small median.

*Pathological report.* — Glandular hypertrophy with marked proliferation.

*Convalescence.* — Some staining, wash water quite red during first twenty-four hours. Tubes and packing

out in forty-eight hours and patient up in chair. Aug. 28, urine passed through penile urethra for first time. Wound closing rapidly, good control. Sept. 3, nearly all urine voided normally, perineal wound nearly healed. Catheter passed, no residual. Discharged twenty-first day.

*Subsequent history.* — May 23, 1910, personally examined in Out-Patient Department. No urinary symptoms whatever. Good control, wound closed. Has bronchitis, otherwise well.

Case 28. W. G. D., No. 167003. E. S. Age, sixty-two years. Single. Farmer. Entered hospital Nov. 19, 1909. Service of Dr. Harrington.

*History.* — No venereal. Has had pain and frequency with burning urination for some months. While on jury duty had retention with overflow dribbling. Catheterized for first time in office Nov. 18 and 32 oz. high-colored urine withdrawn. Bladder three fourths to umbilicus. Clothes urinous. Since catheterization, unable to pass any urine. Comes into Accident Room with bladder again distended to umbilicus. Thirty ounces withdrawn by catheter.

*Examination.* — Fairly well developed and nourished. Right inguinal hernia. By rectum prostate moderately enlarged, soft, symmetrical.

*Urine*, high, acid, clear, albumen 0.

*Cystoscopy* not done.

*Operation*, — ether, — perineal prostatectomy. Small lateral lobes, median lobe pulled down through urethra. One suture to urethra. Usual drainage.

*Pathological report.* — Glandular hypertrophy.

*Convalescence.* — Stormy. Nov. 24, temperature 103. Tubes and gauze out. Urine passes into dressing without control. Epididymitis of both sides, wound septic, some bleeding. Put on constant drainage through urethra and wound packed. Dec. 18, interval urination with control. Residual, 6 oz. Dec. 26, residual down to 3 oz. Very little perineal leakage and good control. Discharged Dec. 28 on the thirty-sixth day.

*Subsequent history.* — March 24, 1910, office note: Feels well. Does not rise at night to urinate. Holds water three hours during day. Good stream, no effort. Has had erections since operation, none before operation for a long time. Urine pale, clear, acid, albumen 0, residual ½ oz. January, 1911, returns to hospital for re-examination. Feels fine, no urinary symptoms, holds water three or five hours in day. Does not rise at night. Good stream, perfect control. Urine clear. Residual less than 1 oz. Has erections. Wound solid.

Case 29. J. G., No. 167326. E. S. Age, eighty-one years. Married. Carpenter. Entered hospital Dec. 11, 1909. Service of Dr. Harrington.

*History.* — No venereal. Always well and strong. One year ago had retention, relieved by medicine. Lately has had difficulty in starting stream. Two days ago retention, was catheterized by local physician. Catheter could not be passed a second time. Silver catheter passed by L. D. with considerable difficulty. Sent to Massachusetts General Hospital.

*Examination.* — Well developed and nourished. Vigorous for his years. Heart sounds irregular and feeble. Knee-jerk present on right, absent on left. Prostate, by rectum, large, firm, symmetrical. Soft rubber catheter tied in urethra.

*Urine*, high, acid, 1024, albumen ½%, sugar 0, sediment — blood and rare leucocyte. Unable to void when catheter was removed. Jan. 1, 1910, patient discharged with catheter tied in, to be under local physician's care. Operation not urged. Jan. 24, 1910, patient re-entered, life unbearable with catheter. Returns for operation.

*Operation*, Jan. 27, 1910, anesthol, perineal prostectomy. Lateral lobes shelled out, no median lobe. Usual drainage.

*Pathological report* missing.

*Convalescence.* — Considerable bleeding. Wound repacked. General condition fair. No bleeding into bladder. Feb. 1, 1910, wicks and drainage out two days ago. Urine voided into perineal dressing. Patient somnolent, slightly uremic. Feb. 4, bronchitis, persistent hiccough, no improvement of general condition, uremic. Feb. 8, condition better, control of urination. Feb. 12, first urine passed through penile urethra. Improving. Feb. 23, residual ½ oz., urine contains considerable pus. Bladder irrigation. March 22, discharged fifty-fourth day. Interval urination through penis. Perineal sinus persists. Good control. Dermatitis due to urotropin?

*Subsequent history.* — Dec. 24, 1910, letter from physician. Patient has been in country without medical care. Urinates about every hour by day and nearly as often at night. Some burning. Urine is cloudy, with considerable sediment. There is a small sinus at the site of wound which discharges a little urine at the time of urination. Good control. General condition has improved.

Case 30. H. W. B., No. 168659. E. S. Age, sixty-eight years. Married. Shoemaker. Entered the hospital March 5, 1910. Service of Dr. Scudder.

*History.* — Gonorrhea at twenty. Two years ago began to have frequency of micturition; this kept getting worse. Finally had retention. Urine drawn by local doctor several times. Treated in the Out-Patient Department for several weeks with catheterization and bladder irrigation without improvement. Residual urine varied from 5 to 9 oz. of foul urine.

*Examination.* — Well developed and nourished. Very nervous. Chest negative. Arteries somewhat hardened. By rectal examination, prostate moderately enlarged, smooth, non tender. Put on constant drainage.

*Urine*, turbid, rather foul, specific gravity 1024, albumen trace, sugar 0, sediment — microscopic blood and pus.

*Cystoscopic examination* in Out-Patient Department: Bladder walls injected and trabeculated. Prostate considerably enlarged. Numerous clots and shreds. March 16, drainage catheter removed. Bladder filled up, patient had to be catheterized again, unable to void.

*Operation*, March 19, 1910, gas and ether, perineal prostatectomy. Usual technic, small lateral lobes removed. No median. Usual drainage.

*Pathological report.* — Glandular hypertrophy.

*Convalescence.* — Gauze and tubes out in forty-eight hours. Control good. No bleeding. March 25, all urine comes through wound. March 31, passing urine through penile urethra. April 4, passing urine naturally with slight leakage through perineal wound. No residual. Urine rather foul. Discharged on sixteenth day.

*Subsequent history.* — Letter, Dec. 26, 1910, reports that wound is healed, there is no leakage, and has good control of bladder; has to get up twice at night; the urine is dark and scanty. Has backache, feels weak and unable to work. Has had no medical treatment.

Case 31. E. D., No. 168797. W. S. Age, sixty-four years. Widower. Farmer. Entered hospital March 10, 1910. Service of Dr. Mixter.

*History.* — Denies venereal. Sciatica three and one-half years ago confining him to bed for three months. For past year there has been increasing urgency and frequency with very slight pain on micturition. Considerable straining. Seven weeks ago passed bloody

urine with great pain. Since then there has been increased frequency and dribbling at night. At times is able to pass only a few drops at a time. For last week symptoms have abated somewhat.

*Examination.* — Fairly developed and nourished. Bladder distended half way to umbilicus. By rectum prostate symmetrically enlarged, firm in consistency.

*Urine* alkaline, specific gravity 1012, albumen 0.

*Cystoscopy.* — Bladder trabeculated, marked intravesical enlargement of both lateral lobes with anterior and posterior sulci. No median lobe, no stone.

*Operation*, March 18, 1910, gas and ether, perineal prostatectomy. Lateral lobes shelled out. In removing intravesical portion of left lobe, floor of bladder torn, also lateral wall of prostatic urethra. Usual drainage.

*Pathological report.* — Glandular hypertrophy.

*Convalescence.* — Wicks and tube out in forty-eight hours. April 1, patient has control, urination through penile urethra. Wound nearly closed. Discharged April 3, sixteenth day.

*Subsequent history.* — Letter of Jan. 8, 1911, states: "I am getting along fine, I think, for I can pass my water as well as I could when I was a boy. The wound is all healed." Since the operation he has felt well enough to remarry, but states that it is a case of "lost manhood."

Case 32. P. G., No. 168773. E. S. Age, forty-eight years. Married. Laborer. Entered hospital March 12, 1910. Service of Dr. Scudder.

*History.* — Recommended from Out-Patient Department with diagnosis of prostatic obstruction. Denies venereal. For three years has been subject to epileptiform seizures. Three since last June. Three years ago began to have difficult and painful micturition. Frequency increased to six or eight per day, six per night, much straining. Never passed any blood. Residual urine of 16 oz.

*Examination.* — Well developed, fairly nourished. Pupils equal and react. Arteries tortuous and palpable. Heart and lungs normal. Double inguinal hernia. Distended bladder palpable above pubes. Rectal examination: Prostate moderately enlarged, soft, smooth. Knee-jerks present. Sixteen ounces of clear residual urine drawn by catheter. No stricture.

*Urine* pale, acid, 1006, albumen 0.

*Cystoscopy.* — Moderate intravesical projection of lateral lobes with slight bar. Bladder wall trabeculated. Patient was examined repeatedly and residual urine varying from 12 to 20 oz. invariably found.

*Operation*, March 18, 1910, gas and ether, perineal prostatectomy. Small lateral lobes shelled out. Finger inserted into bladder, contracted neck felt, dilated with finger. Usual drainage.

*Pathological report* missing.

*Convalescence.* — Tubes and gauze out in forty-eight hours. March 24, stitches removed, wound clean. Passing a little urine by urethra. March 30, residual less than 2 drams. No difficulty in passing urine. No perineal leakage. March 31, discharged, thirteenth day.

*Subsequent history.* — Dec. 27, 1910, patient returns for re-examination. Feels fine, holds water three or four hours during day, rises once or twice at night. Good stream, no pain, perfect control. Full sexual power retained. Urine clear, residual 1 dram. By rectum no prostate to be felt. Operation for double inguinal hernia advised.

Case 34. J. V., No. 169577. W. S. Age, eighty years. Widower. Rope maker. Entered the hospital April 26, 1910. Service of Dr. Mixter.

*History.* — For two or three years, especially during the winter months, has had slightly increasing difficulty in urinating. Since Jan. 1 has had burning pain and some dribbling, has had to urinate every hour or two during the day and every two or three hours at night. One week ago had retention requiring catheterization and again last night.

*Examination.* — Well developed and fairly nourished, does not look his age. Heart and lungs negative. Arteries moderately hardened. By rectum prostate considerably enlarged, fairly hard and firm, almost nodular on right side.

*Urine.* — Smoky, acid, albumen trace.

*Cystoscopy* omitted.

*Operation*, May 3, spinal anesthesia, perineal prostatectomy. Two lateral lobes dissected out. No median lobe. Usual drainage.

*Pathological report.* — Glandular hypertrophy.

*Convalescence.* — Good recovery. No shock or bleeding. Tubes and packing out in forty-eight hours, patient in excellent condition. May 20, no control of urination until to-day. Urine passed through penile urethra. May 26, good control, considerable leakage from wound during micturition. May 28, residual 2 drams. Wound still leaks a little. Discharged twenty-fifth day.

*Subsequent history.* — Out-Patient Department note, June 7, 1910: Good control. Perineal sinus not closed entirely.

Dec. 28, 1910, returns in answer to letter for personal examination. Feels fine, no urinary symptoms. Rises once at night about 4 A.M., holds water three or four hours during day. Stream strong and natural, no pain. Perfect control. Urine clear, no shreds. No erections. Wound healed solidly, no tenderness.

Case 35. S. K., No. 169865. Age, sixty-six years. Married. Tailor. Entered hospital May 14, 1910. Service of Dr. Mixter.

*History.* — Three years ago, at the end of three months of increasing difficulty in urination, patient had retention. He was catheterized for five days by a physician. After that he was able to void, and has had very little trouble beyond slowness in starting stream since then, until last two weeks, when there has been great straining. This morning was unable to void at all, local physician unable to pass a catheter. Sent to the hospital.

*Examination.* — Fairly feeble Hebrew in apparently considerable pain. Chest emphysematous. Moist râles. Systolic murmur. Arteries tortuous and sclerotic. Bladder distended to within two fingers' breadth of umbilicus. Large scrotal hernia. Knee-jerks present. By rectum prostate large, firm and symmetrical. Patient catheterized and large amount of urine withdrawn gradually. Catheter tied in.

*Urine* bloody, acid, 1022, albumen trace, sugar 0.

*Cystoscopy* impossible without anesthesia.

*Operation*, May 24, spinal anesthesia, perineal prostatectomy. Two lateral lobes dug out, no median lobe. Usual drainage.

*Pathological report.* — Glandular hypertrophy.

*Convalescence.* — Tubes and packing out in twenty-four hours. Patient in good condition. May 27, epididymitis. Patient takes very little nourishment. Constant hiccough, uremia. May 31, improvement. Urine comes through wound. June 10, no control of urination yet. Epididymitis better. June 16, with cocaine, scrotum opened and pus of an infected hydrocele drawn off, wound packed. June 20, patient has some control. Scrotal wound granulating. July 2, general condition excellent. Good control. Some leakage from perineal sinus during micturition. Discharged to Out-Patient Department, thirty-ninth day. Residual, 1 oz.

*Subsequent history.* — Jan. 10, 1911, returns for personal examination. Slight pain in passing urine. Frequency about every two hours by day, at night from two to four times. Good control. General health much improved. Much troubled by a large inguinal hernia. Very small sinus persists in perineum, which leaks a few drops on urination. Urine — pale, slightly turbid. Catheter passed, no residual. Has had no local treatment since leaving hospital.

March 9, 1911. Holds water three to four hours. Urine clear without shreds. Residual, 3 drams. Perineal sinus has closed. Has erections at times, is troubled mostly by large inguinal hernia which truss does not retain.

Case 40. C. H. S., No. 171256. E.S. Age, seventy-eight years. Married. Retired. Entered hospital Aug. 8, 1910. Service of Dr. Brooks.

*History.* — For three years has had considerable frequency of urination. Two days ago, unable to void, catheterized by his physician. Catheterized every six hours since. This morning catheterization failed and patient sent to hospital.

*Examination.* — Poorly nourished old man in considerable distress. Marked arcus senilis. Tongue dry and coated. Unhealed carbuncles on back of neck. Epithelioma of tip of left ear. Heart, slight systolic murmur at apex. Lungs, scattered râles. By rectum, prostate considerably enlarged, especially on left side. Silver catheter passed and 12 oz. high colored urine drawn. Put on constant drainage.

*Urine* red, acid, 1015, albumen large trace, sugar 0, sediment—blood and pus.

*Cystoscopy.* — Not attempted on account of bleeding. Aug. 15, taken off constant drainage, passed a little urine naturally, then retention recurred, catheterization became very painful and difficult and caused considerable bleeding.

*Operation*, Aug. 22, 1910, spinal anesthesia, perineal prostatectomy. Lateral lobes shelled out, median lobe shelled out from floor of bladder. Usual drainage.

*Pathological report.* — Glandular hypertrophy.

*Convalescence.* — Good recovery. No bleeding. Sept. 6, wound clean and granulating. All urine comes through wound, but with good control. No note of residual. Patient is anxious to go home. Discharged fifteenth day to local doctor.

*Subsequent history.* — Letter of Dec. 28, 1910, states that wound is healed, there is no leakage of urine, passes water naturally without pain, holds it three hours during day, two hours at night. Has complete control of his bladder, urine is clear. General health is good.

*(To be continued.)*

## New Instrument.

### A NEW TONSIL-SEIZING FORCEPS.

BY LOUIS ARKIN, M.D.,

*Visiting Physician to Ear, Nose and Throat Department, Mount Sinai Hospital, Boston; Assistant Visiting Physician to Ear Department of Boston Dispensary.*

Although there are many kinds of tonsil-seizing forceps now on the market, my apology for the following two illustrations and description is that the instrument is simple and is very effective for its intended purpose in the operation for the enucleation of the faucial tonsils with the cold snare.

The hooks or seizing part may be suited to the individual taste. The two modifications, which have been made by F. H. Thomas Co., by which this instrument differs from similar instruments, are (1) the opening (see A) of a little less than one eighth of an inch in each ring of the handle, and (2) the bend on the flat of the instrument (at B), so that the handle or proximal part of the forceps is in about the same parallel direction with hook or distal part, and both parts in the same plane.

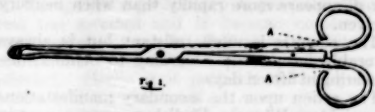

Fig. 1.

The cuts in the rings of the handle are not new, but are of great advantage in slipping the right sized loop of wire over the handle of the forceps when it seizes the tonsil. The advantages of the second modification are two: (*a*) The shape of the instrument easily conforms itself to the contour of the field of operation in such a way that the handle of the forceps does not at any time obstruct the view of the operator when using the forceps in the left hand to seize the left tonsil and in the right hand to seize the right tonsil; and (*b*)

Fig. 2.

to have the hooks of the forceps point in the proper direction to engage the tonsil, a *direct* thrust of the instrument with the operator's arm is used (as the proximal and distal parts are in parallel planes), instead of using a *side pressure* force, which method (as without the modification of the bend) causes pressure pains on the fingers that grasp the forceps, and the hand obstructs the view more or less. This advantage is clearly brought out in removing deep-seated or imbedded tonsils.

## Medical Progress.

### PROGRESS IN DERMATOLOGY.

BY HARVEY P. TOWLE, M.D., BOSTON.

(Concluded from No. 15, p. 545.)

#### CHAPTER 3 — CLINICAL STUDY.

Neisser has summarized the results obtained by the use of Ehrlich's remedy as follows.

"The visible symptoms retrograde and disappear in the most surprising fashion in nearly every case. The initial lesions become soft and lose their induration; in them and in the large condylomata as well it is often impossible to find the spirochete after twenty-four hours; the macular syphilides, the hard papular and the small papular syphilides, ordinarily so resistant, grow pale and become reduced to simple pigmentary spots; mucous plaques disappear; the large, indurated ganglia become soft and small; gummata are resorbed and their painful phenomena disappear; the ulcerations of tertiary or malign syphilis clear up within a few days

and are rapidly covered in; the paralyses and pains of cerebral syphilis disappear in a stupefying manner within a few days and, without exaggeration, within several hours."

In cases of chancre, epidermization is complete; according to Schindler, in two days; to Schultz, in five to eight days; to Gluck, in eight or nine days; and according to Michaelis, in one to three weeks. Microscopically, the induration persists, but disappears more rapidly than when mercury is given.

The adenitis is more resistant but is always favorably influenced; according to Schultz, disappearing in fifteen days.

The action upon the secondary manifestations is variable. Whereas Ehrlich reports a case in which the roseola vanished within three hours, Michaelis had cases in which it persisted from two to twelve days, while Hügel and Ruete encountered two cases in which the exanthem was resistant to treatment.

The Herxheimer reaction has been observed to occur in very different degrees of intensity and with very different doses. According to Herxheimer, the reaction fails in the majority of cases, which is a proof, in his opinion, of the superiority of "606" to mercury. He says that with mercury the reaction occurs because the drug kills only a portion of the spirochete and causes endotoxins to be liberated. No. "606," on the contrary, kills all perhaps without the formation of these toxins. Pellier, however, calls attention to the fact that the directly opposite contention has been used many times to explain other phenomena and especially the death of the syphilitic newborn. Loeb has seen a Herxheimer reaction of unusual intensity occur within two hours after the injection, reaching its maximum in twelve hours and disappearing with the roseola two to four days later.

Neisser asks if this reaction is the result of the death of the spirochete with the liberation of endotoxins or of a sort of stimulation of the parasites which, not being destroyed, produce endotoxins more abundantly. Ehrlich favors this latter hypothesis; it characterizes an active process and, consequently, indicates that the dose was insufficient.

The rapid healing of mucous plaques in an average time of from two to four days is universally admitted.

The papular syphilides yield less readily. Spiethoff is the only one who has seen them disappear more rapidly than the roseolæ. Wechselmann and Sieskind both remark upon the resistance of the large papular elements. Sieskind found the lichenoid forms more amenable. The explanation given for the resistance offered by the large papular forms is based upon anatomicopathological grounds. In lesions with abundant plasma cell infiltration and marked proliferation of the fixed tissue cells, the therapeutic remedy can easily reach the parasite because the vessels remain permeable. On the other hand, the vascular obstruction produced by the endarteritis blocks the entrance of the parasitotrope.

It is hard to estimate the percentage of recurrences both because of the difficulty of following up the cases and also because of the relatively short period since the introduction of "606." The responses to the inquiry of the *Medizinische Klinik*, however, show their relative frequency.

"There have been recurrences and there have been refractory cases, but their number has been relatively minimal." Thus Wechselmann reports 900 cases with 4 failures to respond to the first injection and with 2 incomplete results. Grouven failed to cure an extensive papular syphilide with two injections of 0.3 and 0.6 gm. Michaelis failed in an ensiform syphilide with 0.4 gm. A patient of Halberstaedter's had a marked recurrence of mucous plaques.

Volk thinks "606" superior to mercury in the secondary syphilides and particularly in the ulcerative lesions. In the palmar and plantar syphilides, their effect is about equal. In the macular and papular exanthems he believes mercury to act the better. This opinion is corroborated by E. Hoffmann.

Wechselmann has obtained good results with "606" in the treatment of the pigmentary syphilide which is notoriously resistant to mercurial treatment.

Gross vouches for the extraordinary efficacy of "606" in cases with ocular lesions, such as iritis, kerato-iritis, scleritis and chorioretinitis.

The raucous voice, whether due to erythema of the vocal cords or to papular or ulcerative lesions, yields rapidly. Glück has seen it disappear in one day, and in only one of his 14 cases did it last so long as twelve days. This one case was of a patient twelve years old who received but 0.2 gm.

"Malign syphilis and the ulcerating syphilides are the triumphs of arsenobenzol." Aside from the rare cases in which a second injection has been necessary to complete the epidermization, there is no discordance upon this point.

Three cases reported by Wechselmann illustrate the extraordinary influence of "606" upon the pains in the bones. These cases had resisted all manner of cures with the mercurials and the iodides and atoxyl and arsacetin as well. From the first or second night they were able to sleep, a condition which one of them had not known for five years. The curative action upon the osseous gummata is quite as remarkable. So rapidly do they heal that Ehrlich was lead to remark at the Königsberg Congress that it was impossible that anatomical modifications should have already taken place. That raises the question if these painful phenomena should not be attributed to the products of secretion by the spirochete. The disappearance of the pain could then be explained on the ground that "606" acts as an antineuralgic by combining with the toxin. It would be equally possible, however, to assume that such a combination acts in the manner of an antitoxin.

But, Ehrlich adds, this point of view is contradicted by certain observations in which the contrary effect resulted, i. e., the exacerbation of the pain.

Numerous cases of rapid healing of cranial gummata have been reported.

Herxheimer reports a gumma of the tonsil healed in three days with 0.3 gm.; of multiple gummata of the palatine arch in ten days with 0.45; in a gumma of the testicle resistant to mercury, improvement the day following. In some laryngeal gummata, however, it is to be noted that although there was considerable improvement, there was not *restitutio ad integram*.

All experimenters have been justly cautious in treating cases with ocular lesions. Nevertheless, Sieskind has treated with success optic neuritis of syphilitic origin.

Similarly, an undesirable action has been feared in the presence of cardiac affections. Wechselmann and Nikolai, who made a serious study of the effect of "606" upon the heart, noted no unfavorable action; rarely there occurred a lowering of tension. They have treated aortics without ill-effects, while Sellei has seen the pain disappear in an aortic with angina pectoris. On the other hand, Ehrlich reports a case of death from the rupture of an aneurysm and recommends extreme care in vascular affections.

Neisser reports a surprisingly rapid disappearance of all subjective and objective symptoms in a case of cerebral syphilis with optic neuritis, diverse ocular paralyses and intense cephalgia. Treupel obtained similar results in a recent case of apoplexy with bilateral ptosis and paralyses of the lower members. These results were confirmed by Von Zeisel, Wechselmann and Max Meyer.

In *tabes au début* the fulminating pains sometimes disappear very promptly. Alt and Nagelschmidt have noted, however, that at first the pain is aggravated. Therefore Nagelschmidt adopted the scheme of giving small doses at intervals and reports remarkable improvement. On the other hand, Max Meyer and Sellei obtained no results whatever.

In a woman seven months pregnant Glück reports that fetal movements ceased the day following the injection of "606."

Wechselmann has treated 5 cases of pemphigus neonatorum. Two were cured. Three died within a few days. At autopsy one showed miliary gummata of the liver; one, gummata of the heart; the third, although in a markedly atrophic state, showed no signs of intoxication. Death in these cases is attributed to an enormous discharge of endotoxins, although it must be remembered that most of these cases die under any treatment. In support of this hypothesis is quoted the statement of Reinke who, by Levaditi's method, could find no spirochete anywhere in the organs of a hereditary syphilitic, who died four days after the injection, except in the lungs and, even there, the parasites suggested agglutination.

Taege reports a case of an infant who developed a pemphagoid eruption nine days after birth. The mother received an injection of 0.3 gm. and within five days her infant was free from eruption. Inasmuch as but infinitesimal quantities of arsenic could be detected in the breast milk, the result could not possibly be attributed to arsenobenzol. Ehrlich's explanation is that the liberated endotoxins caused the production of antitoxins which were absorbed by the infant through the milk.

These observations led Scholtz to test the effect of serum obtained from a syphilitic forty-eight hours after receiving an injection of "606." Five cases were so treated. In two, the exanthem and papules disappeared almost completely. In three, after a preliminary improvement, progress was arrested and it became necessary to resort to mercury. In all five the motility and number of spirochete was only temporarily affected. Hence it is probable that only antitoxins had been formed.

As to the consequences of the injections, the pain upon intramuscular injection made the confinement to the bed counseled by prudence a necessity. This pain may last two or three weeks and require morphia for its relief. Care in making the solution exactly neutral and in reducing its bulk has succeeded in diminishing the pain of the injection to a very considerable extent. Kromeyer even succeeded in lessening it so that it was no greater than the pain ordinarily observed in injections of insoluble mercurials.

The injection is usually followed by a rise in temperature even as high as 104° (Schreiber) or 105.4° (Sieskind). Schreiber states that the more recent the infection, the higher the temperature. Various cutaneous eruptions (such as erythema, desquamation and urticaria) may follow the injection. Diarrhea and vomiting have also been observed.

In regard to the accidents which have been reported to have followed the use of "606," opinions differ as to whether they should or should not be attributed to the remedy.

E. Hoffmann reports an alarming weakening of the heart with fever, accelerated pulse, dyspnea, dullness at the base of the right lung and slight albuminuria which followed the injection of 0.3 gm. of arsenobenzol. Hoffmann attributed these alarming symptoms to an embolus consecutive upon a thrombosis produced in the gluteal muscles by a strongly acid solution.

Bohac and Sobotka report three accidents in 14 cases following the injection of an alkaline, methyl-alcohol solution. In one case there appeared four days after the injection nausea, vomiting, constipation, tenesmus and retention of urine which lasted four days. Ten days after the injection there was loss of patellar and Achilles reflexes. In a second case after 0.5 gm. there was violent pain, fever, rectal tenesmus and a retention which lasted nine days, while the cremasteric, abdominal and patellar reflexes were absent. His third case showed similar constitutional symptoms with retention of two or three days' duration and diminution of the patellar reflex on the left with complete absence on the right. The writers wondered if this large percentage of accidents in their small series might not be due to some change in the medicament. This Ehrlich denied and maintained that they were due rather to imperfect technic.

Likewise the cases of a double lesion of the sacral plexus reported by W. Pick and Eitner were ascribed to a faulty technic.

In a case of death reported by Fraenkel and Grouven following the intravenous injection of 0.4 gm. in 15 ccm. dilution, Ehrlich attributed the fatal result not to the mode of injection, but to the predisposition of the subject caused by the conditions in his central nervous system, the autopsy showing that there were areas of softening in the temporal lobes.

Various other nervous complications have been reported, for example, temporary ocular trouble (Spiethoff); an epileptiform attack four hours after injection in an old epileptic.

The only case which Ehrlich admits as not necessarily caused by a pre-existing malady is that of a very anemic woman presenting rebellious manifestations of laryngeal syphilis, formerly treated by atoxyl, who was found dead in her bed the day after the injection. At autopsy there were found no signs of intoxication; the liver showed cicatrized gummata; there was hyperplasia of heart and aorta. According to Ehrlich, the cause of death was the shock of the pain due to an acid solution joined to a certain degree of toxicity. All the other fatal cases, Ehrlich states, occurred exclusively in those who had serious affections of the nervous system, who even without the injection were "*candidats à la mort.*" Altogether about a dozen fatal cases among general paralytics and tabetics have been reported.

In his investigation of the action of "606" upon the nervous system, Willige found that of 35 cases, 5 had died. The dose had been 0.5 to 0.6 gm., and in one case, 0.8 gm. One was the case reported by Fraenkel, mentioned above; three others could not be directly attributed to the arsenobenzol; but the fifth (cerebral syphilis) presented symptoms of acute arsenical poisoning, and arsenic was recovered from the blood and organs.

Ehrlich formally denies optic accidents. "Not a single case of amaurosis has been reported to me and, in spite of the most energetic search, it has been impossible for me to find one case as a basis for the current rumors."

Busche concludes that the remedy, presented as non-toxic, may cause paralysis or depression of the nervous system by acute arsenical intoxication. Schreiber, however, rejects Busche's statements on the ground of faulty technic. All those who have seen cases treated with "606" have been astonished by the enormous proportion of intoxications to the total of cases treated. One may question whether, many times, the long manipulations preceding the injection have not resulted in the introduction of pathogenic germs. For example, Wechselmann got severe manifestations with three injections made in an asylum, while in the Virchow Hospital the preparation bearing the same number was borne perfectly.

*Indications and Contra-indications.*

In his last circular Ehrlich recommends the immediate intravenous injection of a minimum dose of 0.5 gm. in cases of chancre, especially if the patient is young and vigorous. He considers it rational to add also an energetic local treatment, such as extirpation, cauterization, etc.

No "606" is especially indicated in severe ulcerative forms; in malign syphilis; in palmar and small follicular syphilides; in cases refractory to mercury with frequent relapses or presenting an idiosyncracy against mercury.

In general, cases of extensive degeneration of the central nervous system are to be avoided. Alt's advice is to use "606" in general paralysis and in tabes only at the "very first aura" of symptoms. Cardiac lesions, especially angina pectoris and aneurysm, contra-indicate its use.

Although arsenobenzol may be useful in the treatment of iritis, it should not be employed if there are symptoms of atrophy of the optic nerve.

Affections of the viscera, especially if syphilitic, offer no contra-indications. Indeed, the results in syphilitic nephritis have been remarkable.

Cachexia may be favorably influenced by "606." Tuberculosis, unless in a very advanced stage, also does not contra-indicate the treatment.

*Elimination* is by way of the urine and the intestinal tract. In the urine, elimination begins very quickly, especially after an intravenous injection. According to Greven, elimination is completed more rapidly after subcutaneous injections than after intramuscular. Fischer and Hoppe found that it terminated in twelve to fifteen days in general paralytics and sooner in epileptics whose kidneys functionated well. They found arsenic in the blood from the twelfth to the fifteenth day.

The long continuance of elimination after an intramuscular injection is sufficiently explained by the persistance of the arsenic at the seat of the injection. Ehrlich demonstrated in his experiments upon fowls that the arsenic content of the necrotic tissue diminished progressively. In man, Orth demonstrated that the local effect of the injection was an extensive necrosis of the tissues. The time given for the duration of the elimination of arsenic varies within wide limits even up to seven weeks (Scholtz).

*Wassermann reaction.* — The study of the effect of arsenobenzol upon the Wassermann reaction has afforded rather discordant results. Moreover, the percentages have been based upon very different cases. For example, Lange first stated that in 51 cases the reaction became negative in nearly all within four weeks, but, later, in 260 cases, the reaction changed from positive to negative in only 153 cases. Glück observed the change in 5 cases out of 20; Meyer, in 4 paralytics out of 12; Wolf, in 1 in 9.

Iverson found the reaction to have disappeared in all cases in from twenty to forty days. Schreiber, at the end of fifty days, found only 84.6% negative. Neisser and Kuzmitsky obtained a negative reaction in 44% with the Wassermann technic and 19.2% with Marg's modification. Stern, Ailleurs and Neisser obtained only 10%.

The reaction may remain positive for a long time in patients clinically cured and may become

positive in patients with initial lesions who gave a negative sero-reaction at the time of the injection.

According to Lange, the reaction decreases in intensity gradually and at a rate dependent upon the initial intensity.

It has seemed to Hugel and Ruete that reactions which have become negative with "606" became positive again more rapidly than when this result has been obtained by mercurial treatment.

As regards the question of the therapeutic mechanism of "606," as to whether it is really a *sterilisatio magna*, arguments have been advanced on both sides. On the one hand, the hyperthermia is explained by Ehrlich by the hypothesis that it is the result of the liberation of endotoxins. On the other hand, the cure of a nursling by the milk of the injected mother argues in favor of the formation of antitoxins. Moreover, it is pointed out that autopsies upon infants dying soon after the injection have proved that the spirochete had disappeared from nearly the whole organism and that those which survived were much changed.

The chief study of the action of "606" upon the parasite has been upon the chancre and the papular lesions. Iverson reports the disappearance of the spirochete in two or three days and from the ganglia in three or four days. On the other hand, Sieskind found them persisting six or seven days. In the papular lesions, often noted as resistant to "606," Hügel and Rueter once found spirochete with perfect motility on the eighth day.

One effect of arsenobenzol rarely spoken of is the marked leucocytosis. Compared with calomel, Herxheimer and Schonnefeld found that whereas the average leucocytosis with calomel was 18,000, with "606" it averaged 28,000.

Without questioning Ehrlich's assertion that "606" is parasitotropic, Blasche maintains that other interpretations are permissible; for example, that it has a selective action upon pathologic tissues even greater than its spirillotropic action. It is also admissible that the properties of the arsenic are augmented or modified by its combination with dioxydiamidobenzol. Moreover, it may be questioned whether the remedy does not act as an antibody, rendering the toxins emanating from the spirochete innocuous.

On the whole, the opinion is unanimously favorable as to the action of arsenobenzol as an antisyphilitic. The question as to whether Ehrlich has attained his object of *therapia sterilisans magna* is, however, generally left open. Neisser accuses insufficient dosage as the reason why this result has been obtained in but a comparatively few cases. Sieskind, on the contrary, says that the failures are due not to insufficient doses, but to the fact that the spirochete, unlike the other spirilli, do not remain in the blood stream. But, says Neisser, "even if syphilis should never be exterminated, it will lose, thanks to the judicious use of the new weapon placed in our hands, perhaps not all but yet the greatest of the horrors which have hitherto been attached to it."

[Although the foregoing review was written some months ago, it is nevertheless applicable to the situation existing to-day. The number of cases reported has increased tremendously, but in the main the doubtful points are the same to-day as when this was written. We have perhaps gained in knowledge in certain directions, but many things still remain unsolved. We are still in the dark as to whether even apparent cures are cures in fact. The questions of dosage and of technic are still under investigation. Much doubt, to say the least, has been thrown upon the assertion of the non-toxicity of "606," and the best preparation for use still remains to be determined.

That "606" does act as an anti-syphilitic is beyond dispute, but it is growing clearer every day that the remedy cannot be used in all cases, and we are gradually learning more about its precise indications.

As time goes on and the use of the preparation becomes more general, we are hearing more and more of its undesirable effects. Whether such accidents can be fairly attributed to "606" is still an open question which our present experience does not yet qualify us to decide. Our only standard in judging of the effects of "606" is our previous experience with mercury. According to this standard, time alone is able to solve many claims now presented for "606."

For the present, therefore, it will be well to withhold any final decision as to the merits of "606" even while admitting its apparent efficacy.

It may be that in addition to the main therapeutic result there will be added some unexpected developments, as they have been called, "by-products." So great is the curiosity excited by "606" both among physicians and the laity that it is possible that the effect will be to drag the question of the prophylaxis of syphilis out into the light of day so that eventually society may openly acknowledge the existence of the disease and acquiesce in effective legislation to prevent its spread.]

## Reports of Societies.

### COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Meeting of Wednesday, March 1, 1911, at 8 P.M.

The President, Dr. George E. deSchweinitz, in the chair.

#### THE ANATOMICAL EXPLANATION OF THE PARALYSIS OF THE LEFT RECURRENT LARYNGEAL NERVE FOUND IN CERTAIN REPORTED CASES OF MITRAL STENOSIS.

By Dr. George Fetterolf and Dr. George W. Norris.

The authors abstract and summarize the thirty-six hitherto clinically reported and autopsied cases of the above-mentioned condition. In view of the fact that so many different explanations as to the exact mechanism of the compression have been described, the authors undertake to arrive at definite conclusions based on a careful study of the anatomic relations in cadavers in which the organs had been hardened *in situ* before sectioning and dissection. They believe that direct

compression upon the aorta by a dilated left auricle is anatomically impossible. There is also no reason for accepting Kraus' suggestion of traction upon the nerve due to right ventricular hypertrophy. Persistent patency of the ductus arteriosus is also of only secondary importance. The indirect mechanism may be a variable one, but when compression is accountable for the recurrent paralysis, it must always be caused by the nerve being squeezed between the left pulmonary artery (which is often dilated) and the aorta or the aortic ligament. If compression is ever exercised by the auricle directly, it can only be by the tip of the left auricular appendix. Full bibliography. Numerous photographs of actual anatomic relationships.

DISCUSSION.

DR. JOHN H. MUSSER: It would seem that the pressure spoken of is similar in action to pressure against a cushion. Under such circumstances one would hardly think this sufficient, unless there was actual disease of the aorta, to bring about such change in the nerve trunk.

DR. FETTEROLF closes: Dr. Norris found one case on record in which at autopsy there were in the left auricle 3,000 ccm. of blood. This illustrates the amount of distention and pressure which can be brought to bear, and we believe that compression can and does account for the nerve paralysis. The fact that in some of the cases the paralysis appeared and disappeared as compensation failed or was restored is confirmatory of pressure as a cause.

## CHRONIC PANCREATITIS; ITS SYMPTOMATOLOGY, DIAGNOSIS AND TREATMENT; BASED UPON A STUDY OF 38 CASES.

DR. JOHN B. DEAVER: There are no pathognomonic symptoms, no short cuts to the diagnosis of chronic pancreatitis. Diagnosis is to be made only by the mental solution of an equation, the factors of which are obtained by three separate lines of inquiry, viz.:

(1) Anamnesis.
(2) The physical examination.
(3) The special tests designed to show disturbances of pancreatic function.

I have divided my cases into two groups according to the presence or absence of gallstones. Of the 73 cases, 35 had stones in some portion of the biliary passages and 38 had none at the time of operation. In these remarks I shall restrict myself to the non-calculous group, believing that these cases will give a truer picture of pancreatic disease *per se*. The series is still not entirely pure, since 12 had demonstrable changes in the gall bladder at the time of the operation. A careful history is of the first importance. The relation of sex to chronic pancreatitis as compared with cholelithiasis is reversed. The leading and most constant symptom is pain, which was absent in only 3 cases. I am inclined to interpret the presence of colicky pain as an evidence of involvement of the bile passages. No definite relation to eating or to any particular articles of food was brought out in this series. The prominence of nausea and vomiting at variable intervals indicates their importance as symptoms of the more severe type of the disease. The third important symptom is jaundice. A certain percentage of the cases of jaundice in pancreatitis is doubtless due to disease of the bile passages or to extension of inflammation from a catarrhal duodenum. All the cases are not to be explained upon mechanical grounds. The jaundice may come on painlessly. It may also be continuous. The surgical importance of these facts cannot be overestimated. When associated with rapid wasting and loss of strength, the clinical simulation of malignant disease of the head of the pancreas is complete, and cases have repeatedly been denied operation under the impression that operative treatment was useless, — a fatal blunder. The treatment of chronic pancreatitis begins with the amelioration of the predisposing cause. While medical measures may suffice for mild cases, and at times for more severe ones, others go from bad to worse under this treatment. Continued loss of weight, persistence of indigestion, recurring exacerbations, jaundice or a lowered tolerance for carbohydrates should cause the physician to advise operation. Especially binding is this if there be associated disease of the biliary tract. Mayo Robson was the pioneer in showing that free drainage of the biliary tract, and through this outlet, drainage also of the pancreatic ducts, would in many instances enable the pancreas to cast off the infection and resume its normal function. This is, in a nutshell, the principle of the treatment. The easiest and most advantageous method of providing drainage is by a cholecystostomy. If for any reason this is impracticable, drainage of the common duct should be carried out. At times, when the closure of the common duct is complete, and likely to be lasting, a cholecystenterostomy may be best. Drainage should be maintained for three or more weeks at least. The surgeon to-day makes the same plea for chronic pancreatitis as he made twenty years ago for appendicitis. Send the cases early before complications create a mortality.

DISCUSSION.

DR. JOSEPH SAILER: While the larger number of chronic pancreatitis must be relievable only by surgical means, there is certain experimental evidence that medical treatment may be of avail. In experiments upon dogs proof of this was obtained by ligation of the pancreatic duct. It was found that the dogs exhibited practically the same symptoms found in the human being suffering from chronic pancreatitis, and to a large extent these symptoms were abated by feeding the dogs with fresh pancreas secured from slaughter houses. The gain in weight and strength of the animals was really in some cases remarkable. It is difficult to explain these results upon a physiological basis, but I am of the opinion that the carbohydrate ferment in the pancreas is responsible, because it has been my observation in a much more limited number of cases than Dr. Deaver reports that the carbohydrate digestion is not as good in these cases of chronic pancreatitis as are the fat and proteid digestion. I think it must be manifest, too, upon theoretical grounds, which I believe is confirmed by operative experience, that there is a considerable number of cases of chronic pancreatitis in which operation is necessarily of no avail. Particularly is this true in that large group of chronic pancreatitis in which the parenchyma of the pancreas is not particularly affected, but in which the islands of Langerhans are sclerosed, associated with a severe form of diabetes. In those cases of acute pancreatitis with toxemia it has seemed to be desirable to discover whether there has been absorption of some particular toxin in the blood. I think that such a discovery would open up a new field for the study of pancreatic conditions. I have not felt that any of the methods that have been suggested, particularly by the German experimenters, for immunizing animals against toxins, are really of scientific importance.

DR. JOHN H. MUSSER: It would be interesting to learn from Dr. Deaver what proportion of cases presenting symptoms of chronic pancreatitis, and operated upon, were found to be free from pancreatic disease. Also, I should like to ask whether he has found in the

course of the disease the occurrence of sudden anemias, or the sudden exacerbation of the secondary anemia, that usually attends the disease. I have felt that the presence of pigmentation was of value and I should like to know whether in Dr. Deaver's experience this has any significance.

Dr. Deaver, closing: I confess that I cannot see any philosophy in the medical treatment of chronic pancreatitis. I make the statements contained in my paper without hesitancy and I believe they are statements that any man will make if he handles 73 or 75 cases of pancreatitis in the living body. Dr. Sailer's observation in regard to the carbohydrate digestion has been similar to my own. He further says that in certain cases, operation is of no avail. This is quite true. These are the late cases; the time has gone by. Chronic pancreatitis is due to a degree to places such as Carlsbad. We surgeons who are delving into the recesses of the abdomen know that Carlsbad brings us gallstones plentifully. If this is true, why not the results of gallstones, — disease of the pancreas. Dr. Musser raised the question as to what proportion of cases was diagnosed before operation. The only certain way to diagnose chronic pancreatitis is to open the belly. Those of us who do not advise opening the belly are taking an undue advantage of the confidence of our patients. As to sudden anemias, these we have not met with, nor with pigmentation.

Dr. Musser: You misunderstand my question; I asked whether there were many cases of disorder, presumably due to disease of the pancreas, which upon operation were found not to be due to pancreatic disease.

Dr. Deaver: I would say that about half of the cases were diagnosed before operation.

### MALPOSITIONS OF THE COLON, WITH SPECIAL REFERENCE TO THEIR CONGENITAL ORIGIN.

(Lantern demonstration.)

By Dr. Floyd E. Keene (by invitation).

Malpositions of the colon with the production of angulation is the underlying factor in the production of fecal stasis. With the idea of determining a possible relationship between the conditions existing during early life and those found in the adult, twenty-five autopsies were performed on infants. In the light of these observations, together with the clinical history so often associated with these malformations, we are warranted in concluding that, with but few exceptions, the conformations of the infant's colon correspond closely with those of the adult. The primary cause of vicious angulation productive of chronic constipation lies in some developmental abnormality of the colon. These angulations may be active from the earliest months of life or a faulty mechanism may perform its function normally until some extraneous cause, such as childbirth, lingering illness or trauma, converts what may be termed a potential angulation into an actual obstruction by disturbing the intra-abdominal equilibrium, which permits sagging of the intestine with the formation of kinks at the junction of a fixed and movable segment.

### WHAT CASES OF ANATOMICAL DEVIATION OF THE GASTRO-INTESTINAL TRACT ARE AMENABLE TO SURGICAL TREATMENT.

Dr. John G. Clark: From the observations of my associates, Dr. Floyd E. Keene and Dr. Ginsburg, on the embryologic and anatomic defects occurring in the gastro-intestinal tract, it is quite evident that many of the supposed cases of functional constipation have a long existent anatomic etiology. As we have analyzed the types of constipation we find that relief by surgical means is largely applicable to this particular class. It is farthest from our intention to hold out the view that the neurasthenic individual of constipated habit can be relieved by surgical measures. The necessary differentiation between what might be classed as a functional and a pathologically anatomic constipation is not always easy. My rule is to ascertain, first, the duration of the constipation, as to whether congenital or acquired; and, second, as to the means necessary to effect an evacuation of the bowel. The summary of the entire question hangs upon whether there is a definite anatomic defect constituting a partial obstruction. In the order of topographical observation of colonic defects, we have noted the colicky pains incident to a decensus of the cecum which, instead of resting at the brim of the pelvis, drops as a dilated pouch into the cul-de-sac. Wilms ascribes these pains to the failure of peristalsis and antiperistalsis to carry the food content upward, and finally past the hepatic flexure into the transverse colon. According to our viewpoint, however, we are more inclined to ascribe these symptoms to a defective emptying of the ileum into the cecum. When we first began to apply the x-ray to these cases for diagnostic purposes, we were inclined to view many cases as being seriously anomalous which we have since considered approximately normal. Treves many years ago pointed out the fact that one fourth of all autopsies showed the dependent loop of transverse colon well below the umbilicus, and he interpreted this as a significant possibility in the production of excessive degrees of constipation. As a result of our clinical experience, however, we view these cases only from the standpoint of the functional coefficient of the colon, for every surgeon has noted even exaggerated degrees of colonic ptosis without any marked degree of constipation. It is not possible, therefore, to establish an anatomical rule for the treatment of these cases, and it is not for the surgeon to initiate the treatment. Only upon medical failure can we justifiably accept these as surgical cases, and even then we must be guarded in our promises of relief. In my service at the University Hospital we have operated upon over fifty of these cases. Of this number we can claim 48% of cures. Of the remainder, some are improved, others are no better. These, however, represent the exaggerated types. Although not yet accepting with enthusiasm Lane's principle of radical extirpation of the colon with anastomosis of the ileum into the sigmoid, I am sure that in the exaggerated cases, where there is great redundancy and dilatation of the colon, occasionally this measure alone offers hope of relief. One cannot, however, be too careful in advising operations in such classes of cases, for we have all witnessed the operative mania instituted in cases of movable kidney and the gross misapplication of gastro-enterostomy in the hands of the operative novice or enthusiast who wields the scalpel with greater facility than he exercises his judgment.

### DISCUSSION.

Dr. John H. Gibbon: After what Dr. Keene and Dr. Ginsburg have shown us I believe it is probably impossible to say exactly what is the normal colon. The colon may appear to be very anomalous and yet be capable of performing functions. The cases to be operated upon are the cases giving rise to definite symptoms. I feel that Mr. Lane has gone beyond all reason in recommending and performing operations upon the colon. I think that the occasional operator, or the young man, needs to exercise much care in the selection of cases for operation. It took us some time

to learn that neurasthenia was not caused by movable kidney and not cured by operation upon it. If we follow Dr. Clark's advice we shall not go far wrong.

DR. S. SOLIS-COHEN: I should like to ask whether in this interesting study there has been found any large proportion of cases with narrowing of the lumen of the large intestine for a considerable distance. Occasionally in autopsies upon such cases of pulmonary tuberculosis I have observed such narrowing of the whole of the colon. Recently in a number of patients not tuberculous, studied by skiagrams, I have observed along with angulations or misplacements or anomalies, considerable tracts of apparent narrowing with delayed emptying. The question of adhesions arises in the instances of abdominal section; but in others there had been no operative interference. The propriety of resection of the narrow portions for obstruction or chronic pain is worthy of consideration.

DR. GEORGE E. PRICE: Neurologists have found that neurasthenia is more apt to be the cause of gastro-intestinal symptoms than the result of disorders of the digestive tract. The study of congenital anomalies of the gastro-intestinal tract should prove of interest in such conditions as epilepsy, where gastro-intestinal auto-intoxication is a factor of importance; also in the degenerative psychoses. As far as I can recall, no such studies have been made.

DR. JOSEPH SAILER: I think we make a mistake in confusing neurasthenia with malnutrition. Many such patients are not neurasthenic in the popular use of the term, but undernourished. Very often improvement in nutrition will bring about an anatomical correction of the part. Dr. Gibbon said that it took the surgeons a long time to find out that movable kidney was not the cause of neurasthenia. I have only to remind him that this was not for the lack of telling, for in a very able paper published in the early nineties the whole subject is carefully discussed.

DR. JOHN B. SHOBER: In 1898 I had the honor of reading before this college a paper upon "Anomalous Positions of the Colon, with the Report of a Case Discovered at Exploratory Operation." I had reviewed the literature and reported some fifty cases embracing all the types represented to-night and the conclusions then reached were much the same as to-night. A point in etiology not mentioned this evening was that many of the malpositions were considered to be the result of peritonitis occurring in fetal life, forming adhesions which would interfere with normal development and result in all kinds of deformities.

DR. JOHN B. DEAVER: I do not believe that post-operative dilatation of the stomach is due to any anatomical arrangement of the blood vessels and so forth; I believe it is due to infection or toxemia.

## Book Reviews.

*The Problem of Race Betterment.* By J. EWING MEARS, M.D., LL.D. Philadelphia: William J. Dornan. 1910.

This book consists of three papers (the first published in this JOURNAL for Oct. 21, 1909) all bearing on the subject of asexualization of idiots, criminals, defectives and perverts, to which is appended a short essay on the desirability of applying this procedure by law to certain classes in the community. The author prefers ligation of the spermatic cord to vasectomy for this purpose. The book is to be regarded in no sense as final, but merely as a polemic expressing the writer's opinions on a question which popularly and medically is still *sub judice*.

*A Textbook upon the Pathogenic Bacteria for Students of Medicine and Physicians.* By JOSEPH MCFARLAND, M.D., Professor of Pathology and Bacteriology in the Medico-Chirurgical College, Philadelphia. With 211 illustrations, a number of them in colors. Sixth edition, thoroughly revised. Philadelphia and London: W. B. Saunders Company. 1909.

Within the past decade several pathologies of a high order of merit have been published by American scientists. In no department of medical science does America take a higher rank than in bacteriology. This advanced standing is reflected in the textbooks, and in our judgment there is no better textbook on medical bacteriology in all its aspects than the standard work of McFarland, which in this last edition he has revised with customary thoroughness.

*A Textbook of Pathology.* By JOSEPH MCFARLAND, M.D., Professor of Pathology and Bacteriology in the Medico-Chirurgical College, Philadelphia. Second edition, thoroughly revised. Four hundred and thirty-seven illustrations. Philadelphia and London: W. B. Saunders Company. 1910.

The first edition of this work appeared in 1904. The author states in the preface of this new edition that within the year preceding its issue the work was gone over from cover to cover and a thorough revision made. It contains an enormous amount of information and is a book characterized by clear and concise statement. A striking feature is the wealth of illustrations, which have been carefully selected from a great number of standard textbooks and special articles. It is a work more adapted to the needs of the clinician than to those of the undergraduate student in pathology. The sections dealing with pathological histology, especially cytology, are insufficient for the worker in a present-day laboratory.

*Organic Analysis Chart.* By W. HARRISON MARTINDALE, Ph.D. A supplement to the Extra Pharmacopœia. Fourteenth edition. London: H. H. Lewis. 1910.

This is a chart, in book form, relating to the recognition of organic chemical bodies used in therapeutics. The plan is one of elimination by the application of a number of systematic tests with heat; heat and NaO.H; $H_2SO_4$, cold and with heat; $HNO_3$; nitrogen, phosphorus, sulphur and halogens tested for in the usual manner; specific gravity and solubility; ferric chloride; alkaloidal reagents, etc.

The reviewer has not had the chance to try the schemes of tests, but the plan of elimination adopted by the author has the appearance of much value.

THE BOSTON

# Medical and Surgical Journal.

THURSDAY, APRIL 20, 1911

*A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.*

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.*

*All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.*

*Remittance should be made by money order, draft or registered letter payable to*

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

## RESTRAINT OF THE INSANE.

The care of the insane and particularly of those who through the character of their maladies are difficult to control has for many years been a subject of interest to lay humanitarians and to physicians. The matter of restraint and the form such restraint should take has been recognized as a problem of fundamental importance and also as one impossible of solution through any general formulation of rules. Those who have studied and written on the subject have differed somewhat widely as to what constitutes restraint and as to how much and under what conditions it should be employed, but the definite result of the investigation of the past years has been an increasing disuse of force in the care of the insane. This has been brought about partly through the influence of public opinion, but much more through the efforts of the superintendents and those in charge of insane hospitals, who have clearly seen their problem and met it fairly. As a result, restraint of any sort has been reduced to a minimum, but that minimum remains and doubtless will remain as long as insanity takes on forms of extreme violence.

Legislation in the matter is clearly unnecessary and, in fact, harmful to the best traditions of medicine as a profession and of society at large. Medical treatment, whether of the insane or of the bodily sick, must be left to the judgment of the specially trained and not to any arbitrary outside authority whatever. If malpractice results, the offender may be called to account through the ordinary processes of law, and not otherwise. Only by training men for special work and then trusting them completely is the greatest efficiency to be secured.

It is, therefore, regrettable that a bill should have been introduced into the Massachusetts Legislature, by Dr. L. Vernon Briggs, which aims "to prohibit certain forms of restraint on patients in public or private hospitals or sanatoriums." A hearing on this bill was held last week before the Committee on Public Charitable Institutions. It was largely attended and the bill met a practically united opposition on the part of the medical profession, including the superintendents of hospitals. Those who spoke in favor of the bill were the petitioner, Dr. Albert Evans, several clergymen whose knowledge of the actual conditions was evidently inadequate, and one or two others. The argument of the proponents, in general, was that restraint was rarely necessary and when required should be administered in a certain way fixed by law under penalty of fine. In other words, the superintendent of a hospital, who, under existing conditions, is wholly responsible for the care and treatment of his patients, is to be held to account for the proper performance of his duties by legal enactment, thereby curtailing his initiative and freedom of action. The clergymen who spoke were moderate in statement but were inclined, as the bill itself does, to assume conditions which do not exist.

The opposition was vigorous, searching in its criticism and at times indignant. Dr. Henry R. Stedman, chairman of the Board of Trustees of the Taunton Insane Hospital, showed that only a fraction of one per cent of insane patients in hospitals were under any form of restraint during a recent month. He felt that the bill struck at the roots of efficiency by restricting the powers of the authorities. Dr. George T. Tuttle, of the McLean Hospital, regarded it as doubtful policy to prescribe by law how sick persons should be treated. Dr. H. W. Mitchell, of the Danvers Hospital, summarized the significance of the bill in saying that "it substituted legislation for medical intelligence." Dr. George W. Gay, who represented The Massachusetts Medical Society, and Dr. John G. Blake, senior physician at the City Hospital and trustee of the Gardner State Colony, spoke with some indignation regarding the implications of the bill and the consequent reflection on the medical profession. Dr. George L Walton adequately refuted the charge brought by Mr. C. W. Barron that Massachusetts was twenty years behind the times in the treatment of its insane by reading a letter from John Koren, expert special agent of the Department of Commerce and Labor, in which he stated that Massachusetts stood foremost among the states of the union in the care

and treatment of the insane. Dr. Owen Copp, executive officer of the Massachusetts State Board of Insanity, showed by statistics that the amount of restraint has steadily decreased in Massachusetts during the past fifteen years and that the number of patients under any form of restraint is well under one per cent.

In general, the discussion at the hearing showed that the greatest activity has prevailed for many years in reducing forcible restraint and that Massachusetts has had an enviable record in this regard. No evidence was adduced to show the necessity or even desirability of legislation such as that proposed in Dr. Briggs's bill, which in last analysis really does not prohibit restraint, but simply legalizes it. The best results in humane treatment can undoubtedly be secured by appointing the very ablest men obtainable to the positions of medical responsibility in our hospitals and by trusting them implicitely to enforce the necessary discipline among their subordinates. It is also desirable to secure attendants of a high degree of fitness and to provide adequate remuneration for their services. Under these conditions, it is not to be doubted, as has been proved by the experience of the past, that the future will show continued progress in the treatment of the mentally afflicted.

## THUCYDIDES AND THE ATHENIAN EPIDEMIC OF PLAGUE.

THE epidemics of bubonic plague which, for a good part of the winter, prevailed in the orient, and in certain places are still unchecked, have revived interest in some of the earlier famous historic pestilential appearances of this scourge. In the issue of the *Münchener Medizinische Wochenschrift* for March 14, Dr. Schröder summarizes the account given by Thucydides of the epidemic which broke out at Athens in 431 B.C., the opening year of the Peloponnesian War. The infection apparently traveled from Ethiopia, Egypt and Libya to Persia, and thence in ships to the European continent. In Greece it first broke out at Piraeus, the port of Athens, and spread thence to the upper city. In both places it found favorable ground for its development, owing to the overcrowding of the city with Attic refugees, the lack of hygiene, the inadequacy of food.

Thucydides describes most vividly the symptomatology and clinical course of the disease. The first signs were headache and redness and inflammation of the eyes. Soon there appeared bleeding from the mucous membranes, cough, extreme fever, unquenchable thirst, pallor, collapse, coma, death. Many died after a short sickness. Those in whom the disease lasted a week or ten days developed numerous ulcers on the body, and profuse diarrhea. Few recovered.

Though Thucydides had nothing to say about etiology, he seems to have recognized the infectious nature of the plague, for he observes that those who tended or approached the sick were most liable to the disease. No treatment then devised had any power over the infection, and in the absence of any sanitary measures of prophylaxis, it ran its course among the people unchecked. How many perished is not known. Pericles himself died of it in 429 B.C. Probably the demoralization as well as the actual number of deaths it caused contributed in no small measure to the defeat of Athens in the war and her ultimate downfall. The story told by Thucydides, like Defoe's "History of the Plague Year in London," is a classic of medical description and deserves to be known as one of the earliest extant contributions to the knowledge of this great oriental scourge.

## SCIENCE AND METHOD.

IN the issue of the JOURNAL for Jan. 5, we noted an address by Dr. Charles S. Minot, of Boston, before the American Association for the Advancement of Science, on "The Method of Science." Dr. Minot emphasized particularly the growing precision of science both in observation and in deduction. The current issue of *Science* for April 14 contains an extended critique of his paper and reply to some of his assertions. Its writer, Prof. S. M. Patten, of the University of Pennsylvania, considers Dr. Minot's address "a new presentation of a topic fully discussed from the attitude of pre-evolutionary thought, but in such manner and from such premises that its logic cannot serve as a basis for present problems." With the increasing accuracy of means of observation, research under the new science has reduced itself to a series of experiments and measures. The tendency is to regard these as ultimate and to consider that there is little likelihood of error or fallacy in deductions from them. But this is what the writer of the critique believes often to occur. In enthusiasm over method, over the mechanical recording of data, the observer loses his perspective, makes arbitrary deductions and fails to grasp the far-seeing human generalization that

includes all the elements involved. In the perfection of our means of observation, we are prone to concentrate our attention on them and go astray in a hopeless field of irrelevant detail, losing sight of the real meaning and importance of the question under study. Method is essential, but after all it is only the machinery of science, whose directing and motive agent should be a broad and constructive rationalism.

## INTERNATIONAL CONGRESS ON HYGIENE AND DEMOGRAPHY.

In the issue of the Journal for Feb. 16, we published an editorial giving preliminary announcement of the Fifteenth International Congress on Hygiene and Demography, which it is proposed to hold in 1912 at Washington, D. C. Further information relative to this Congress has now been received. The date has been set for the week of Sept. 23–28, 1912. Invitations to participate in the Congress have already been accepted by twenty-two foreign governments, including Argentina, Austria, Belgium, Brazil, Cuba, Denmark, France, Germany, Great Britain, Greece, Holland, Hungary, Italy, Japan, Mexico, Norway, Russia, Spain, Sweden and Switzerland. The governors of the several states of the union have also been invited to appoint each a state committee of not more than five members to co-operate with the National Committee on Organization. Active membership in the Congress is open to any person interested in public health or vital statistics, on payment of a fee of $5, which also entitles him to participate in the proceedings and to receive a copy of the published transactions. The continuity of the Congress with those that have preceded it is maintained by a permanent international commission, with headquarters at Berlin.

## DISTRIBUTION OF SPOTTED-FEVER TICK.

In Circular No. 136 of the Bureau of Entomology of the United States Department of Agriculture, issued on March 31, F. C. Bishopp describes and illustrates by a map "The Distribution of the Rocky Mountain Spotted-Fever Tick, *Dermacentor Venustus*." This insect occurs most thickly in the northern part of the Rocky Mountain region in the United States, the frequency of its distribution in the several states in decreasing order being as follows: Montana, Idaho, Washington, Wyoming, Colorado and Oregon, Utah, Nevada, California, New Mexico. The immature ticks live almost exclusively on small mammals, and adults on large domestic animals. A subgenus of ground squirrel is probably a very common host. Since it has been demonstrated that this wood tick is the principal if not the sole agent in transmitting Rocky Mountain spotted fever to man, the knowledge of the extent of its dissemination is important, for it will facilitate measures to control the tick in regions where it already exists and to prevent its introduction into uninfected areas.

## MEDICAL NOTES.

Alleged Discovery of a New Element. — It is reported from Cincinnati, Ohio, that Prof. C. T. B. Fennell, of the University of Cincinnati, has made preliminary announcement of his discovery of a new element similar to radium. The details of this alleged discovery have, however, not yet been made public.

New Jersey State Hospital for the Insane. — The thirty-fifth annual report of the managers and officers of the New Jersey State Hospital for the Insane at Morris Plains records the work of this institution for the year ending Oct. 31, 1910. During this time 519 new cases were admitted and 460 patients were discharged, leaving 2,118 inmates in hospital at the close of the year.

Use of the Kinematograph in Medicine. — It is reported from Philadelphia that at a recent meeting of the Alumni Association of the Philadelphia Medico-Chirurgical College, kinematographic plates were employed to illustrate a lecture by Dr. Theodore H. Weisenburg on "The Gait, Station, Tremors and Other Symptoms of Various Forms of Nervous Disease." The possible applicability of this method to use for the obtainment of physical records which might be valuable for subsequent reference and for didactic purposes was suggested by Dr. Walter G. Chase, of Boston, in an article on "The Use of the Biograph in Medicine," published in the issue of the Journal for Nov. 16, 1905 (Vol. cliii, p. 571).

Longevity of British Physicians. — The issue of the *British Medical Journal* for April 1 contains obituaries of three English physicians, Dr. Thomas Reid, of Glasgow; Dr. William Paley, of Peterborough, and Dr. Thomas Dobson, of Leeds, at the ages of eighty, ninety-four and ninety-three years respectively. Doubtless this is an exceptional coincidence, but it would seem that in England the profession

does not wear out those in its service so prematurely as is often unfortunately the case in our own country.

A LIVING ENGLISH CENTENARIAN. — It is reported from London that, on April 10, Mrs. Henry Essex Bristow, of Southwark, celebrated the supposed one hundred and fourth anniversary of her birth. She is said to be in excellent health. As her son is a canon of Southwark Cathedral, the tale of her longevity may undoubtedly be accepted as veracious.

THE END OF THE BROWN DOG OF BATTERSEA. — In the issue of the JOURNAL for March 24, 1910, we published, on page 406, an account of "The Brown Dog of Battersea," an effigy intended as a protest against the supposed sufferings of animals at the hands of medical experimenters. From time to time since that date there have been notices, in various English journals, of contentions that have arisen over this statue and of attempts to deface, remove or protect it. It is now finally announced that "pursuant to an order made on March 8 by the Battersea Borough Council, the brown dog has been broken up and the inscription on the base of the monument erased."

MR. ROOSEVELT AND "WILFUL STERILITY." — In a recent editorial in the *Outlook*, Mr. Roosevelt returns to the consideration of race suicide and the numerical regulation of the American family. The "new nationalism," he declares, demands that every household should contain at least four children. Upon all which fall below this irreducible minimum will come the "curse of wilful sterility." Whatever may be the validity of Mr. Roosevelt's new nationalism, his ideas about race suicide seem at bottom pretty sound, and as a coiner of apt phrases he is almost as felicitous, though not so prolific, as his kindred spirit, Mr. Kipling.

IMPORTANCE OF DISINFECTION AFTER INFECTION. The monthly bulletin for February of the Illinois State Board of Health, in an article on "Disinfection after Infection," quotes as follows from an opinion recently handed down by the Supreme Court of Maine:

"Where the public health and human life are concerned, the law requires the highest degree of care. It will not allow of experiments to see if a less degree of care will not answer. . . . No more are those in charge of smallpox patients allowed to experiment to see how little cleansing will answer; how much paper bedaubed with smallpox virus it will do to leave upon the walls of the rooms where the patients have been confined. The law will not tolerate such experiments. It demands the exercise of all possible care. In all cases of doubt, the safest course should be pursued, remembering that it is infinitely better to do too much than to run the risk of doing too little."

This statement, continues the article in question, "might be taken seriously to heart by those sanitarians and health officers who maintain that terminal disinfection is unnecessary, basing their declaration upon the indefensible hypothesis that the majority of the pathogenic organisms speedily die when they leave the patient." Doubtless there is such a thing as wasteful and unnecessary precaution, but even this is better than easy-going negligence.

A GIFT TO COMBAT TUBERCULOSIS. — Report from Chicago announces the gift by James A. Patten, of that city, of the sum of two million dollars to Northwestern University for the establishment of a new chair of experimental medicine, and for the determination and practical application in Illinois of the best methods of controlling, preventing and eradicating tuberculosis. There have been several examples, in recent years, of the devotion of great wealth to the purposes of preventive medicine. It is sincerely to be hoped that in the present instance the results attained may be commensurate with the expectations and generosity of the donor.

LONDON DEATH-RATES IN FEBRUARY. — In the issue of the JOURNAL for Feb. 23 we commented editorially on the death-rate of London for 1909, and for the last four months of 1910. Statistics just published for February, 1911, show the total mortality of that month in London to have been 17.6 per 1,000 inhabitants living. As we noted in our previous editorial, the rates vary widely in the different districts and boroughs. In February, the highest were 27.6 in the old city of London and 24.3 in Shoreditch at the east end; and the lowest, 10.2 in Hampstead and 12.4 in Greenwich, both situated at the periphery of the city.

## BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, April 4, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 45, scarlatina 42, typhoid fever 4, measles 169, smallpox 0, tuberculosis 57.

The death-rate of the reported deaths for the week ending April 4, 1911, was 19.15.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, April 15, 1911, was 243, against 238 the corresponding week of last year, showing an increase of 5 deaths, and making the death-rate for the week, 18.39. Of this number 117 were males and 126 were females; 232 were white and 11 colored; 152 were born in the United States, 85 in foreign countries and 6 unknown; 57 were of American parentage, 149 of foreign parentage and 37 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 40 cases and 2 deaths; scarlatina, 29 cases and 1 death; typhoid fever, 5 cases and 1 death; measles, 186 cases and 2 deaths; tuberculosis, 39 cases and 27 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 33, whooping cough 2, heart disease 24, bronchitis 6. There were 17 deaths from violent causes. The number of children who died under one year was 39; the number under five years, 53. The number of persons who died over sixty years of age was 81. The deaths in public institutions were 104.

Birth-Rate in Lynn. — Vital statistics from Lynn, Mass., for the year 1910, show that during that year there were only one hundred more births in the city than during 1909, the increase of population being largely by immigration. The births were least numerous among native Yankee families.

Protection of Fruits in Lynn. — It is reported from Lynn, Mass., that the local board of health has issued an ordinance requiring all fruit-dealers in that city to provide henceforth suitable covering for all berries and other fruits exposed on their stands, to prevent contamination by dust or flies.

Scarlet Fever in Beverly. — On April 10, two cases of scarlet fever were reported in a tenement house at Beverly, Mass. The house is located in a densely populated part of the city, and to prevent spread of the infection, the entire building, with its twenty-two occupants, has been quarantined by the local board of health.

Needs of the Infants' Hospital. — On the afternoon of next Tuesday, April 25, a bridge tournament is to be held at Hotel Somerset, and in the evening a pop concert for the benefit of the Infants' Hospital. The new building of this institution is now being erected on grounds near the Harvard Medical School, but a considerable sum of money is still needed for its completion, equipment and maintenance.

Connecticut Conference on Charities and Corrections. — The annual Connecticut State Conference on Charities and Corrections will be held at New Haven, Conn., next Monday, April 24. Addresses before this meeting are to be made by President Charles W. Eliot, on "The Social Evil"; by Prof. Irving Fisher, on "Public Health"; by Mr. Charles Hendricks, on "Pollution of Streams and Harbors"; and by Dr. J. H. Kellogg, on "Tendencies towards Race Degeneration."

Massachusetts Homœopathic Medical Society. — The annual meeting and dinner of the Massachusetts Homœopathic Medical Society, held in Boston last week, were attended by about two hundred members and guests. The following officers were elected for the ensuing year: President, Dr. Frank W. Patch, of Framingham; recording secretary, Dr. Edward S. Calderwood, of Roxbury; corresponding secretary, Dr. Benjamin T. Loring, of Boston; treasurer, Dr. Thomas M. Strong, of Boston.

Some Recent Medical Bequests. — The will of the late Sullivan Niles, of Cambridge, Mass., allowed in the Middlesex Probate Court last week, contains a bequest of $3,000 to the Cambridge Hospital for the foundation of a free bed in memory of the testator's son.

Among other bequests in the will of the late Dr. Henry Lyman Shaw, of Boston, filed last week for probate, is one of $200 to the Perkins Institution for the Blind, and three of $100 each to the Massachusetts Medical Benevolent Society, the Boston Medical Library, and the Children's Island Sanatorium at Cat Island, Marblehead, Mass.

Procedures under Pure Food and Drug Laws. — In the municipal court at Boston last week three dealers of this city were sentenced respectively to three months' imprisonment, one month's imprisonment, and a fine of $30 for having in their possession, with intent to sell, a case of rotten eggs and three bags of sugar containing a large amount of sand. They all appealed. Before the same court a Chinese merchant of Boston was arraigned and held in $300 bail on the charge of illegal delivery of opium. Before the United States District Court at Boston, another druggist of this city was fined $150 for

shipping to Philadelphia last July a consignment of "infant syrup" whose content of morphine was not distinctly stated on the label. On the same day, the United States deputy marshal seized at a wharf in Boston, whither it had been sent by a New York firm, a shipment of eight barrels of acid calcium phosphate intended for use as baking powder, but alleged to be adulterated with calcium sulphate and arsenious oxide.

WORK AND PROGRESS OF THE BOSTON DISPENSARY. — In the issue of the JOURNAL for April 6 we published a brief note on the "work and needs of the Boston Dispensary." The recently issued annual report of the Dispensary describes in greater detail the activities of this institution for the year 1910. Of the 40,000 patients treated by the Dispensary during the year, 16,000 were children. Last fall a children's hospital, with 16 beds, was established at 64 Tyler Street in conjunction with the Dispensary. The board of managers has recently appointed, as director of the institution, Mr. Michael M. Davis, Jr., Ph.D., of New York City, a graduate of Columbia University, who has had considerable experience in that city as a settlement worker, social student and publicist. Under his administration, and with increased financial support by the public, the hope is expressed that the Dispensary will be able to continue and extend its admirable work in the service of the community of Boston.

## NEW YORK.

BEQUEST TO THE GERMAN HOSPITAL AND DISPENSARY. — By the will of the late Bernard G. Amend, of New York, one of the heads of the well-known firm of Eimer & Amend, druggists and manufacturing chemists, $2,000 is left to the German Hospital and Dispensary.

BEQUEST TO THE PRESBYTERIAN HOSPITAL. — On April 11, in the New York Supreme Court, under Justice Bischoff, the Presbyterian Hospital won a legacy of $120,000. The jury decided that the will of Edward O. Kindberg, dated Oct. 27, 1908, and leaving the bequest to the hospital, was valid, while a second will of March 25, 1909, omitting the bequest, was invalid because of lack of testamentary capacity.

THORACIC SURGERY AT THE GERMAN HOSPITAL. — The new pavilion for thoracic surgery at the German Hospital was thrown open for inspection on April 8, when Dr. Willy Meyer, the surgeon in charge, explained the very ingenious apparatus. Here is "the latest thing" in chambers for operating under positive and negative air-pressure, and each chamber is placed in an ordinary operating room, so that, if this should for any reason be deemed advisable, an operation can be continued under other methods, the patient remaining on the same table.

SOCIAL SERVICE AT THE NEW YORK DISPENSARY. — The New York Dispensary, the oldest in the city, which since its establishment in 1790 has given medical and surgical aid to more than three million patients, has recently organized a Social Service Department. In common with other workers in a similar field, the trustees have recognized the futility of effecting a cure and then returning the patient to the same conditions that produced his illness. This department makes hospital treatment, where necessary, possible for a wage-earner by seeing that through established agencies his family is cared for in his absence, perhaps finds more healthful employment for him, and otherwise renders him friendly aid. In consequence of the increased expenditure which all this involves, the dispensary has felt constrained to make a special appeal for contributions.

LINES TO A TYPHOID FLY. — According to a writer in the New York *Times*, the ghost of the author of the well-known "Lines to a Fly," after seeing the moving pictures with which Prof. Frederic S. Lee, of Columbia University, illustrated one of the lectures in his recent popular course on Modern Medicine at the American Museum of Natural History, was moved to make alterations in them as follows:

Most injurious typhoid fly,
Drink with you no more will I.
When you settle on my cup,
I, perchance, bacteria sup.
After what I've seen to-day,
I would have you chased away.

I dislike those feet of thine;
What they've touched I shall decline.
Carrier of germ and spore,
Get thee hence! Return no more!
Spreader of disease, begone!
Kindly leave my food alone.

MORTALITY STATISTICS FOR MARCH. — The weekly reports of the Health Department show that during the month of March the mortality in the city represented an annual death-rate of 17.73, as against 16.60 in February and 17.69 in March, 1910. Among the diseases in which there was an

augmented fatality were the following: The weekly average of deaths from measles increased from 14.5 in February to 17.5 in March; the weekly average from scarlet fever, from 20.5 to 29; from diphtheria and croup, from 31 to 35.5; from pneumonia, from 158 to 166.25; from bronchopneumonia, from 117.75 to 146.75; from diarrheal diseases, from 49.25 to 64.75; from diarrheals under five years of age, from 44 to 62; from cirrhosis of the liver, from 22.25 to 29.25; from Bright's disease and acute nephritis, from 118.75 to 128; and from puerperal diseases, including septicemia, from 14.75 to 16.75. Among the diseases in which there was a diminished mortality were the following: The weekly average of deaths from influenza declined from 24.25 to 16.25; from pulmonary tuberculosis, from 193.5 to 182.75; from apoplexy and softening of the brain, from 28.5 to 24.75; from organic heart diseases, from 182.75 to 165.25; from appendicitis and typhlitis, from 12.25 to 10; and from hernia, intestinal obstruction, from 12.75 to 9.5. During the month there were six deaths from malarial fevers, while in February not a single death was recorded from this cause. The corrected death-rate, excluding non-residents and infants under one week old, was 16.77.

3. Fry states that facts point to a local infection of the jaw bone by phosphorus through diseased teeth as the essential factor in necrosis in phosphorus poisoning. From the observation of 177 persons for from six months to two and one-half years it seems evident that the measures in operation at the present time are effectual in the prevention of necrosis in persons employed in the manufacture of matches from white phosphorus and that the substitution of other less satisfactory materials is unnecessary. These methods consist chiefly in trying as far as possible to exclude from phosphorus factories persons with decayed teeth, in the rigid frequent inspection of those employed and the requiring all defects of teeth to be treated thoroughly as soon as discovered. The method is a prophylactic one and is very successful, as shown by the fact that out of 177 cases observed over a period of two and a half years, only 8 cases of necrosis have developed.

5. Mayo emphasizes very strongly why gallstones should never be looked upon as innocent but should always be removed when known or suspected to exist. Early operation is relatively safe and the gall bladder may be saved for future function. Simple operation for uncomplicated gallstones has a mortality of less than 0.5%, and this mortality, even, is due to the condition of the patient rather than to the operation. Mayo, in his series, has found complications in more than two thirds of his cases. Carcinoma was associated with gallstones in 85 cases (2.25%). Gallstone disease sometimes causes serious circulatory disturbances. Endocarditis is sometimes coincident with a gallstone attack and each exacerbation of the gallstone disease is accompanied by an increase of cardiac symptoms, which can be relieved to some extent by relief of the gallstone disease. Quiescent gallstones often become active during pregnancy. Some women can identify gallstone attacks with certain pregnancies. Eighty-six per cent of all diseases of the pancreas seen by Mayo at operation were complicated by gallstones. Seven per cent of all patients with gallstones in the gall bladder operated on have had pancreatitis in some form, and in 27% of cases of stone in the common duct marked pancreatitis was present. Pancreatic complications were four times more frequent in cases of common duct stones than in cases in which stones were still in the gall bladder. The function of the gall bladder does not seem to be a storehouse for bile since as much bile is secreted in twenty-four hours as there is urine, but it probably acts to take the pressure off the common and hepatic ducts as shown by their marked distention and dilatation after removal of the gall bladder. There is every reason why one should operate early for gallstones and preserve the gall bladder as often as possible. [E. H. R.]

### The Archives of Internal Medicine.

March, 1911.

1. Thayer, W. S., and Peabody, F. W. *A Study of Two Cases of Adams-Stokes' Syndrome with Heart-Block.*

6. Novak, E., and Whitney, E. L. *Acute Yellow Atrophy of the Liver; Report of Two Cases.*
7. Von Pirquet, C. E. *Allergy.*

5. Hart proposes a simple method for estimating the degree of acidosis in diabetes and other conditions. The method depends upon the intensity of color developed by adding ferric chloride to urine containing the acetone bodies. Two solutions are necessary: (1) The "standard solution," consisting of ethyl acetate 1 ccm., alcohol 25 ccm., water 1,000 ccm.; and (2) ferric chloride solution, consisting of 100 gm. ferric chloride dissolved in 100 ccm. water. The technic is as follows: Take two test-tubes of equal caliber, put in one 10 ccm. of the "standard solution" and in the other 10 ccm. urine, add to each

1 ccm. ferric chloride solution, allow the tubes to stand two minutes and then compare the color. Dilute the urine until the colors match, noting the volume to which it has been necessary to do so. By this means we obtain the "acidosis index per liter" in accordance with the following schedule:

Volume of urine, 10 ccm. Index per liter, 1.

Volume of urine, 20 ccm. Index per liter, 2, etc.

In order to ascertain the "acidosis index" proper, multiply the index per liter by the number of liters of urine passed in twenty-four hours. In support of this "index" the author presents tables comparing results obtained by this and other methods in forty-one cases of acidosis. He claims for it the value of a simple and quick means of following the daily fluctuations of organic acid excretion. [L. D. C.]

## ANNALS OF SURGERY.

### MARCH, 1911.

12. HIBBS, R. A. *An Operation for Stiffening the Knee-joint.*
13. WATTS, S. H. *Intussusception in the Adult.*

3. Brewster and Robinson report a case of bullet wound of the heart and review the literature on wounds of the heart. They find 177 reported cases of heart wounds, 71 successfully sutured and 106 operated with fatal result. Of these cases only 24 were bullet wounds (including their own), with recovery of 11 and death of 13. These 24 cases are carefully tabulated. Their own case is described in detail (symptoms, examination, operation and post-mortem). The bullet had apparently pierced the fifth left rib near nipple line, entered pericardium, traversed cavity of left ventricle, penetrated diaphragm, then passed through left lobe of liver, again through diaphragm, penetrating lower lobe of left lung and becoming imbedded in intercostal muscles at back. They advocate long intercostal incision under differential pressure with spreading of the ribs. In regard to drainage they believe it wiser to suture the pericardium tightly. Subsequent aspiration may be performed, if pericarditis ensues.

4. Long makes a plea for the preservation of the gall bladder. He argues that (1) many cases upon which cholecystectomy is frequently done do equally well with simple cholecystostomy, (2) the mucus secreted by the gall bladder reduces the toxicity of the bile, and (3) cholecystenterostomy is at present the only means of dealing with chronic pancreatitis. The frequency of pancreatitis in common duct cases (24%, Mayo) persuades Long not to sacrifice the gall bladder unnecessarily.

7. Cobb and Giddings report a case of cystadenoma arising from a supernumerary kidney, which grossly as well as microscopically resembled a normal one, i. e., was fully developed with its own blood supply, but without a ureter. The patient is in excellent health one and one-half years after removal. Seven cases of supernumerary kidney are collected from the literature.

8. Moore and Corbett have used rabbits to determine the amount of kidney destruction following various methods of suturing the split kidney. Simple suture of the capsule proved unsafe on account of hemorrhage. Mattress sutures caused tissue destruction far beyond the field of operation and enlargement of the unoperated kidney. This enlargement was due to simple congestion and not to increase in kidney tissue. This method, therefore, reduces the sum total of kidney substance. Interrupted deep sutures transfixing the kidney at the pyramidal line and tied around the body of the kidney did the least damage. The authors recommend this type of suture. Photomicrographs are given.

11. Alexander considers various phases of the subject, line of cleavage, relation of base of prostate and bladder, middle lobe, control of hemorrhage, bladder drainage and general post-operative treatment. The technic of operation is given in detail, with numerous hints for contending with the unexpected. [T. W. H.]

## THE LANCET.

### MARCH 11, 1911.

1. *GOADBY, V. W. *The Hunterian Lecture on the Association of Disease of the Mouth with Rheumatoid Arthritis and Certain Other Forms of Rheumatism.*
2. HASLAM, W. F. *Lettsomian Lectures on Operation for Stone in the Male Bladder. Lecture III.*
3. LANE, W. A. *The Principles on which the Treatment of Resting Conditions of the Skeleton is Based.*

10. SINGER, C. *A Forgotten Prophecy of the Microbic Theory of Infectious Disease.*
11. BENTHALL, A. *The Question of Compulsory State Insurance of Employers' Liability under the Workmen's Compensation Act, 1906.*

1. Goadby adds an interesting contribution to the work already done on chronic infectious joint disease, and the mouth as portal of entry for the infecting organisms. He briefly classifies those joint diseases, which he considers of infectious origin, especially the rheumatoid group. He then summarizes the clinical evidence tending to show that there is a connection between pyorrhea alveolaris and such joint lesions, and reviews the work on the bacteriology of the subject by Fayerweather, Painter, Poynton, *et al.* He describes the morphology and cultural characteristics of the organisms found and the results of many inoculation experiments on animals as to joint lesions produced by these organisms. He describes the results of treatment by autogenous vaccines, and strict attention to the local mouth condition.

5. Harris has made a careful bacteriological study of the feces of twenty-seven typhoid patients and from his researches concludes that typhoid carriers cannot be such a large factor in spreading the disease as was thought possible when one considers the comparatively large numbers of typhoid patients discharged who undoubtedly have active typhoid bacilli in their stools. [J. B. H.]

### MARCH 18, 1911.

1. *BOYCOTT A. E. *The Milroy Lectures on Ankylostoma Infection. Lecture I.*
2. KEITH, A. *Hunterian Lectures on the Anthropology of Ancient British Races.*

6. TURNER, P., AND CATTO, H. C. *The Iodine Method of Sterilizing the Skin.*
7. SELIGMAN, C. G. *An Egyptian Holy Man.*

1. In the first of the Milroy Lectures, Boycott describes the life history of the ankylostoma and the modes of infection with special reference to skin infection. He devotes special attention to the duration of infectivity; this may last four to six years after the original infection. He discusses at length the pathology of ankylostoma anemia; this seems to consist of an apparent decrease in hemoglobin but a real increase in the total blood mass, which accounts to a large extent for the apparent deficiency in hemoglobin. The color index is low and morphological changes slight. The exact cause of the anemia is not known; it is probably due to a destructive action on the blood by the worms themselves.

4. Gibbard and Harrison add one more article to the long list of those dwelling on experiences with "606," its method of administration and results obtained from its use. [J. B. H.]

11. COOMBS, C. *The Histology of Rheumatic Carditis and Other Rheumatic Phenomena.*
12. NICOLL, W. *The Rat Flea as the Intermediate Host of a Rat Tapeworm.*

3. Parker describes an epidemic of 37 cases of infantile paralysis in Bristol, England, from June, 1909, to January, 1910, and compares it with other epidemics here and elsewhere.

4. Vipond discusses the etiology of poliomyelitis, with particular reference to its similarity to typhoid fever. Both diseases occur in the late summer or fall months; cold weather causes both diseases to disappear; the incubation periods of each disease are the same and the Widal reaction is often positive in poliomyelitis. His observations are interesting, but not conclusive.

5. Verdon believes that the attack of angina pectoris is due to gastric distention causing pressure on branches of the sympathetic system going to the heart. He cites many cases where attacks of angina seemed to be of gastric origin and were relieved by belching of gas; from statistics he believes it to be proved that coronary sclerosis has nothing to do with causing the attacks of angina, though the consequent weakened condition of the heart indirectly may lead to death in these cases. Coronary sclerosis, thrombus and embolism, he considers to be the result rather than the cause of angina pectoris.

8. Evans comments upon the results of forty-four cases of syphilis treated with "salvarsan." [J. B. H.]

DEUTSCHE MEDIZINISCHE WOCHENSCHRIFT. No. 10.

MARCH 9, 1911.

3. In the literature now are beginning to appear answers to the question that was so frequent, namely, Will the symptoms of syphilis return after a while following treatment with salvarsan alone? Bettmann in this article reports recurrences which have occurred under his observation. In some cases the character of the skin lesion is quite characteristic.

4. These authors have found in nine cases with tuberculosis of the lungs, skin or glands a distinct cellular reaction at the site of the tubercular process after an injection with salvarsan. They could not detect any helpful effects from this reaction, but think that it suggests the possibility of a therapeutic influence. [C. F., JR.]

MÜNCHENER MEDIZINISCHE WOCHENSCHRIFT. No. 11.

15. KOWARSCHIK, J. *A New Four-Celled Bath-Controller.*
16. SCHRÖDER. *The Clinical Picture of the Plague in Thucydides.*

1. The writers have tried Carl Beck's method of stitching malignant tumors to an open wound and treating them directly with the Röntgen rays. They have reached the conclusions that by this procedure the tumor may be treated with better results, that the danger of burns to the skin and injury of other organs by the rays may be avoided, that the general condition may be improved and the comfort of the patient promoted.

2. Schottmüller in earlier work stated that the hemolytic streptococcus of erysipelas was found in puerperal fever. He now adds that the anaërobic streptococcus putridus is equally common and that the staphylococcus aureus, the B. coli and the B. phlegmonis emphysematosæ are far less important.

5. Neu says that for post-partum hemorrhage there is no better drug than suprarenin. It acts on the muscles of the uterus independently of its effect on blood-pressure. It produces tetanic contractions of the uterus and increases its muscular tone and irritability for a considerable time afterwards. He has used intramuscular and subcutaneous injections to induce labor, to increase the strength of labor-pains and to stop hemorrhage. Pituitin has an entirely similar but weaker action. [G. C. S.]

REVUE DE CHIRURGIE.

MARCH, 1911.

1. *BROCA, A., AND ROLAND, E. *Treatment of Papillomata of the Larynx in the Child.*
2. *BÉJAN, J., AND COHN, M. *Experimental Study on Ligature of the Inferior Vena Cava.*
3. CHAVANNAZ, G., AND NADAL, P. *Mixed Tumors of the Thyroid Body.*
4. *COTTE, G., AND ARNAUD, L. *Treatment of Biliary Perforations into the Free Peritoneum in the Course of Lithiasis.*

1. From a theoretical discussion, the authors conclude that there is no satisfactory treatment for papilloma of the larynx in children. They consider extraction by the natural route, under control of the mirror, as the operation of choice, but recommend tracheotomy at any time in the event of dyspnea. When such extraction is impossible, they advocate thyrotomy or thyrostomy. Stricture of the larynx should be treated by laryngostomy.

2. After reviewing the work of Purpura, of Gosset and Lecène, and of Liotta in experimental ligation of the inferior cava in animals, the writers report the results of their own series of twenty such similar procedures, with the following conclusions: (*a*) Life is possible and compatible with full health after ligature of the inferior cava at any point below the renal veins. (*b*) Ligature of the inferior cava including one of the renal veins is well tolerated. The circulation of the involved kidney is readily established through the veins at its superior pole by anastomosis with the corresponding suprarenal vein, the abdominal parietes and the diaphragm. (*c*) Ligature immediately above the renal veins and involving the left suprarenal is equally compatible with life. The circulation is re-established by the venous plexus at the superior pole of each kidney, and thence by the suprarenal directly with the vena cava on the right, and on the left by anastomoses of this vein with the diaphragmatic veins, the abdominal parietes, the lumbar, azygos and spinal veins. (*d*) Ligature above the right suprarenal is always fatal.

4. Cotte and Arnaud collect from the literature 76 operated cases of biliary perforation into the peritoneal cavity during lithiasis, and in a comparative study of these, discuss the chemical and anatomic data, the therapeutic indications, and the results of surgical intervention. Of the cases in this series 42 died and 34 recovered. In simple cases, they advocate merely drainage; in cases complicated by grave infection, cholecystectomy and drainage. [R. M. G.]

4. ANTONELLI, G. *Icterus Gravis with Demonstration of Bacillus Paratyphosus Beta in the Blood and the Spleen.*

2. Pontano reports an exhaustive clinical study of the so-called cobra reaction of blood serum. He finds that the property of activating cobra venom belongs to the sera of persons suffering from tuberculosis and other diseases. It is not especially characteristic of tuberculosis either febrile or afebrile and is far inferior to the ophthalmic and cutaneous tuberculin tests. The activating substance (probably lecithin) cannot be demonstrated any more often in the sera of tuberculous cases than in that of various other diseases. The cobra reaction should, therefore, be discarded as a diagnostic test for tuberculosis. [L. D. C.]

## Obituaries.

### EDWARD FITCH CUSHING, M.D.

DR. EDWARD F. CUSHING, of Cleveland, a distinguished graduate of the Harvard Medical School, died on March 23, from a malignant

obstruction of the colon. He was in his forty-ninth year. Dr. Cushing's acute illness lasted but a few days; indeed, he was busy about his work up to a week before his death. A sudden and unexpected intestinal obstruction overtook him. It was relieved by operative anastomosis, but he did not rally and succumbed shortly to a double pneumonia.

Dr. Cushing's death brings upon our profession a serious loss, — and in more than the conventional sense. He was a man of rare attainments, untiring, devoted, courageous. At a largely attended citizens' meeting held in his memory at the Lakeside Hospital, on March 26, a prominent layman called him the most eminent citizen of Cleveland. There were remarkable qualities in the character and career of Dr. Cushing which justify this eulogy. His was one of the brilliant minds of our profession, — acute, observant, retentive. His student contemporaries will not forget his astonishing comprehension, his lucid explanations, his practical applications and his unfailing resourcefulness. He was an omniverous reader and a profound scholar. He ranged widely through our literature, and stored great information, ready for instant and practical use. He was highly trained. After completing a brilliant service as house-surgeon at the Massachusetts General Hospital he received an appointment to the medical service in the same institution, where his work was equally effective. He served as house-physician to the Boston Lying-In Hospital also, and spent time in Europe studying diseases of children. In such fashion was he equipped for his career.

Unlike many other men of fine mind and high attainments, Dr. Cushing was modest for himself and keenly appreciative of the opinions and work of others. He listened to, and assimilated, the views of his colleagues. His intellectual and practical charity were constant and unfailing. He thought no evil. He assumed fair play in others even as he himself practiced honorable dealing. He encouraged effort, though it might come to small ends; and he applauded eagerly every sane, forward, progressive and honest endeavor which might lead to the betterment of medicine.

Throughout his professional life he gave himself to the welfare of the community in which he lived, — without thought for the wider fame which might easily have been his, — but earnestly, faithfully, constantly, for twenty years he devoted his great talents to Cleveland and his native state of Ohio. He accomplished much; his fellow-citizens loved, respected and trusted him; and so he came to hold with them a place almost unique among modern physicians. We all know and respect the highest type of family doctor, — the faithful, devoted friend, the wise counsellor, the sound adviser. Dr. Cushing filled this place in a perfect degree, but he brought to the service those great qualities of brain, as well as of heart, whose loss is mourned by his people.

The outline facts of Dr. Cushing's life appear simple and are soon told: He came of a distinguished line of physicians. His great-grandfather was a physician in New England; his grandfather, Erastus Cushing, was a pioneer and one of the early physicians of Cleveland; his father, Henry Kirke Cushing, a surgeon of the Civil War, practiced medicine in Cleveland almost to the time of his death at the age of eighty-three, less than two years ago. Harvey Cushing, of Johns Hopkins and Harvard, is Edward Cushing's younger brother.

Edward Fitch Cushing was born in Cleveland in 1862; was graduated A.B. from Cornell in 1883 and M.D. from Harvard in 1888. After completing his post-graduate studies he began practice in his native town in 1891, when his father was still active. In the course of years the son took over the father's work. The younger Cushing soon made himself felt in the community. Important assignments were given him, and he created new enterprises. He was visiting physician to the Lakeside Hospital; he fostered the *Cleveland Medical Journal*, which owes much of its success to his leading and his money; he promoted and established the Babies' Dispensary, a splendid work; he was foremost in organizing the Cleveland Medical Library, and in reorganizing the prosperous and distinguished Western Reserve Medical College. In all questions relating to public health his advice was sought and was liberally given. He was a vice-president of the Harvard Medical Alumni Association. Such were a few of his many activities. His life was one of service. He was an ideal clinician, perhaps there was no greater in this country. And with all this, his was a life of self-abnegation. Rarely in this modern world do we see great talents so consecrated to plain duty. We have our professional leaders, our great martyrs to science, our widely heralded surgeons, our Walter Reeds, our heroes of the laboratory; Edward Cushing might have ranked them all, but he chose what seemed a humbler field, — to give himself unreservedly, faithfully, brilliantly to the daily service of the sick. He set a standard which may well be an inspiration and an example to every practitioner, humble or famous, in the land; and in the short space of twenty years he accomplished a work and gained a loyal devotion in a great community which may not hope to see his like again.

## JAMES BELL, M.D.

Dr. James Bell, who died last week at Montreal, Canada, was born in North Gower, Carleton, Ontario, on Oct. 10, 1852. He studied medicine at McGill University, from which he graduated in 1877. During the same year he served as house surgeon of the Montreal General Hospital. In 1881 he was made medical superintendent of that institution, in 1885 he was appointed to its staff as assistant surgeon, and became visiting surgeon in 1886. He served for some years as surgeon to the Sixth Battalion of Fusiliers, and in

1885, during the Northwest Rebellion, did active duty in the field as surgeon major in charge of the hospital corps. In 1888 he was made associate professor of clinical surgery at the McGill Medical School. In 1894 he became professor of clinical surgery and was appointed surgeon-in-chief to the Royal Victoria Hospital and consulting surgeon to the Montreal General Hospital. He was descended from a famous Scotch family of physicians, and was himself distinguished as a teacher and practitioner.

## Miscellany.

### DIFFUSION OF UNIFORM PUBLIC HEALTH METHODS.

IN last week's issue of the JOURNAL we noted the intention of the Bureau of the United States Public Health and Marine-Hospital Service to print from time to time in its weekly reports local municipal ordinances, rules and regulations pertaining to public hygiene, "in order to make them easily accessible for study or imitation by health officials in other communities throughout the country." The public health reports of the Bureau for March 31 and April 7 contain the first instalments of these local ordinances, including regulations from New Bedford, Mass., and New Haven, Conn., relative to poliomyelitis; from Lynn, Mass., relative to the temperature and bacterial content of milk; from Fall River, Mass., relative to milk and to school inspection; from Providence, R. I., relative to the protection of foodstuffs in markets; from Camden, N. J., relative to spitting in public places; and from Minneapolis, Minn., relative to regulation and inspection of hotels, restaurants and boarding-houses. These reprints should afford excellent and valuable means for the comparative study of methods of dealing with the problems of public health and should lead to greater administrative uniformity by the diffusion and general adoption of those methods which in a given community have proved successful and advantageous.

### AMERICAN PHYSICAL EDUCATION ASSOCIATION.

THE annual convention of the American Physical Education Association was held in Boston last week on the four days from Tuesday, April 11, to Friday, April 14, inclusive. On Wednesday evening, April 12, there was a joint meeting of the Association and of the Public School Physical Training Society of Boston; and on Thursday, April 13, the Association was entertained at the Harvard Medical School by the Massachusetts Medical Gymnastic Society. At the various sessions of the convention numerous interesting papers were presented, among others one by Dr. Edward H. Bradford, of Boston, on "Physical Training in the Correction of Scoliosis"; one on "Age," by Dr. Charles S. Minot, of Boston; and one by Dr. George L. Meylan, president of the Association, on "Physical Training in Europe." Addresses were also made by Dr. Thomas F. Harrington, of Boston, and by Dr. C. Ward Crampton, director of physical training in the public schools of New York City. Dr. Dudley A. Sargent, of Cambridge, and Prof. John M. Tyler, of Amherst, discussed "The Physical Education of Girls and Women." Dr. E. A. Peterson, of Cleveland, Ohio, emphasized the importance of the element of play in all physical training. The spontaneous exercise of children and of men is by means of games; many of the serious affairs of life are pursued in the spirit of game; and without this spirit, gymnastic training loses much not only of its educational value, but of its physical benefit.

### INTERPRETATION OF PURE DRUG LAW.

IN the issue of the JOURNAL for April 6 we noted the filing of a demurrer by a certain firm against charges brought against it under the pure drug law. This demurrer is based on a decision recently rendered in the case of Dr. O. A. Johnson by a District Court in Missouri. The indictment in the latter case was quashed on the ground that the pure drugs act does not apply to false statements about the curative properties of medicines, but only to false statements regarding their ingredients. An appeal from this decision is now being argued before the United States Supreme Court at Washington, D. C. Dr. Johnson's counsel contends that if the law be interpreted as forbidding statements about the curative properties of drugs, the act is unconstitutional, since such statements are intended not as statements of fact, but as forecasts of probability. On the other hand, the solicitor-general maintains that the law is constitutional and was intended by Congress to forbid such statements about the supposed remedial virtues of any medicine as would be likely to mislead purchasers into an unjustifiable confidence in its efficacy.

### THE STRASSBURG MUNICIPAL DENTAL CLINIC.

IT is reported from Strassburg, Germany, that during the current month of April, the municipal dental clinic of that city will be for the first time established in new and adequate quarters in connection with the local medicinal baths. This clinic, which was established in 1888, was one of the first in the world to afford free dental examination and treatment to public school children. The work done at Strassburg was imitated in other cities in Germany and throughout the civilized world, as the importance of dental care and oral hygiene, especially in childhood, and its bearing on the general health, came more and more fully to be realized. The establishment of the Strassburg clinic in new and larger quarters is of particular interest in connection with the present plans for the Forsyth Dental Infirmary in Boston.

## BUBONIC PLAGUE IN THE ORIENT.

The international medical conference on the plague, which was opened on April 3 at Mukden, has been in session during the past week; but detailed reports of its proceedings have not yet been received. It is further announced from Paris that a scientific French commission, headed by Dr. Metchnikoff, and composed chiefly of members of the Institut Pasteur, will go in May to Asiatic Russia to make extensive investigations there of the bubonic plague and the possible modes of its prevention. Meantime, report from Amoy, China, states that during the fortnight ending April 8, there were in that city 12 deaths of plague and 5 of smallpox, making a total of 37 deaths from the former and 24 from the latter disease since Feb. 11. From The Hague, it is reported that the epidemic of plague in Java, to which we referred in last week's issue of the Journal, is extending. In the vicinity of Malang, in the eastern part of the island, there are said to have been 46 cases with 26 deaths; and in the region about Batavia, the capital, there are said to have been already nearly 100 deaths from the disease.

## IN MEMORY OF JOHN C. MUNRO, M.D.

The Journal has received the following tribute to Dr. John C. Munro:

The Governing Board and Staff of the Carney Hospital feel that this, the first stated meeting of the year 1911, should not pass without an expression of the sense of sorrow and personal loss they feel in the death of Dr. John C. Munro, late surgeon-in-chief. His services to the hospital were invaluable and were rendered with a willingness and spirit that is worthy of the highest commendation. Honest, kindly and modest, a master of his art, high in his ideals and loyal to the institution, he exerted on his associates, on the public and on the profession at large a splendid influence that cannot well be measured.

The Carney Hospital has sustained a great loss and it is the wish of the Governing Board and Staff that this expression of sorrow and sympathy be sent to Dr. Munro's family and also be spread upon the official records of the institution.

By the Secretary,
John T. Bottomley, M.D.

## EFFECT OF CHOLINE DERIVATIVES ON BLOOD-PRESSURE.

In Bulletin No. 73 of the Hygienic Laboratory of the Public Health and Marine-Hospital Service of the United States, Reid Hunt and R. de M. Taveau report the results of their investigations into "The Effects of a Number of Derivatives of Choline and Analogous Compounds on the Blood-Pressure." Eighty-one such substances were studied, and their effects experimentally determined and tabulated. The importance of this piece of research lies not only in the possibility of discovering substances of therapeutic value, but in the fact that choline is one of the active principles in suprarenal gland secretion, is closely related to neurine, muscarine and other powerful poisons, is found in preparations of ergot and other important drugs, and has long been recognized as a possible source of danger in foods.

## UNFORTUNATE CONNOTATION OF "606."

As a result of Ehrlich's recent synthetic discovery of salvarsan, the innocent number "606" has acquired an unfortunate connotation, which suggests itself not only to members of the medical profession, but to many of the laity as well. It has already been dropped as a telephone number in several exchanges, and seems likely to share the unpopular fate of 13 and 23, though for a different reason.

## MEDICINE AS A "LIGHT BUSINESS."

In the window of a certain building in Boston may be seen the sign: "Rooms to Let. Suitable as Offices for Doctors, Dentists or Other Light Business." The question arises whether the practice of a "Divine Healer," whose office is nearby, would also be classified under the category of "light business."

# Correspondence.

## LETTER FROM THE PHILIPPINES.

Changes in Medical Officers. Taal Volcano Eruption. Annual Meeting of the Medical Association. Polished Rice and Beriberi. Salvarsan in Syphilis and Yaws. Ultraviolet Rays. Amebic Dysentery. General Health Conditions.

*[From Our Special Correspondent.]*

Manila, P. I., Feb. 28, 1911.

*Mr. Editor:* The last month has been a busy one in medical affairs in Manila and has been marked by many changes in personnel at the Philippine General Hospital; by a sudden influx of a large number of emergency cases brought to Manila from the regions devasted by the Taal volcano eruptions; by the annual meeting of the Philippine Islands Medical Association, which held its meetings at the Medical School and hospital buildings.

Although it is difficult to "hurry the East," yet in some respects Manila resembles a new western town in its rapid shifts and changes. During the last month, Dr. Philip K. Gilman has returned from a long vacation in the States to resume his duties as associate professor of surgery in the College of Medicine and Surgery and as assistant visiting surgeon to the Philippine General Hospital. Dr. W. E. Musgrave, professor of clinical medicine, and Dr. Victor G. Heiser, director of health of the Philippine Islands, and professor of hygiene, have started for the States via India and Europe for long vacations. Dr. Richard P. Strong, physician-in-chief of the General Hospital and professor of tropical medicine, has been summoned to China to represent the United States on the International Plague Commission gathered to study the bubonic plague situation. Dr. Donald Gregg, a former house pupil at the Massachusetts General Hospital, has been appointed assistant professor of tropical medicine at the College of Medicine and Surgery, and in the absence of Dr. Strong

is acting physician-in-chief of the Philippine General Hospital.

Early in February, Taal volcano, which lies about thirty miles to the southward of Manila, suddenly became violently active, and after many minor rumblings and earthquakes suddenly blew off its top, causing considerable loss of life and devastation. About thirteen hundred natives were killed in the several small barrios, or villages, which were destroyed by mud, steam and a tidal wave upon the lake surrounding the volcano, and many others were badly burned. For the first time in the history of the Islands, hospital accommodations were to be had to care for the victims of such a tragedy. About ninety cases were rushed to Manila and turned over to the General Hospital for care and shelter. As is usual at such times, the best among the Americans and Filipinos answered the call, responding generously with their time, energy and purses in helping the government care for the sufferers.

The annual meeting of the Philippine Islands Medical Association was held during the past week at the Medical School and hospital buildings. The meetings extended over three days, from Feb. 22 to Feb. 24 and were participated in by medical representatives from the army, the navy, the civil government service and by private practitioners. Papers of especial interest were read upon spinal anesthesia, which has been used with considerable success at Bilibid Prison; upon the relationship between beriberi and a rice diet; upon the use of "salvarsan" in yaws and syphilis; upon the effects of tropical sunlight, and upon the amebæ found in the human intestine.

Dr. Malloy has used stovaine in a large number of cases and considers it to be the anesthetic of choice in operations upon the rectum and prostate. Continued investigation upon the relationship between beriberi and a rice diet has shown conclusively that polished rice, rice freed from its pericarp, can and does cause in chickens and man a polyneuritis which in many cases is diagnosed as beriberi, and that unpolished rice, or a liberal diet of foods other than rice, promptly relieves this condition. Whether this polyneuritis is true beriberi is yet to be determined. At least, it has been proved that much suffering and physical disability among the native people can be remedied and avoided by substituting unpolished rice or a liberal diet for a meagre diet of polished rice such as forms the usual food of the native.

"Salvarsan" has been found by Dr. Strong to be even more astonishing in its seeming curative effects in yaws or frambesia than it is in syphilis. A single injection of "606" produces a complete disappearance of the strawberry-like tubercles on the skin within three weeks.

Further investigation upon the effects of tropical sunlight suggests that the result of the ultraviolet rays has been over-emphasized, and the effect of the ordinary heat rays not properly considered. These conclusions tend to discount the beneficial effects of special colored underwear.

Dr. E. S. Walker, who was previously associated with Dr. Theobald Smith at the Harvard Medical School, and who has been working at the Bureau of Science Laboratory for some months past on the morphology of different strains of amebæ, reports results suggesting that there are varieties of non-pathogenic amebæ which infest the water in the tropics but which probably are not an etiological factor in amebic dysentery. If further researches show that amebic dysentery comes only from fecal infection of food and drink, another health problem in the tropics will be in part solved.

General health conditions in the Islands continue excellent. At present, there is practically no cholera in Manila, and no plague cases have been introduced from the infected regions in China. Some cases of varioloid appear among the natives, and as communication between the Islands and the United states becomes more rapid and common, cases of measles and whooping cough are perhaps less rare than formally. An index of the health conditions in Manila is the fact that at the General Hospital considerable difficulty has been experienced in finding cases of amebic dysentery and malaria to demonstrate to the medical students. Streptococcus infections and associated conditions, such as scarlet fever and erysipelas, continue to be practically unknown. The seeming inability of the streptococcus to thrive in the Philippines is a bacteriological problem wholly unsolved. "G."

## BLEEDING "GRATIS."

BOSTON, April 15, 1911.

*Mr. Editor:* Medical competition of every degree and kind has, like quackery, existed since the birth of the practice of the healing art. In former days, when bleeding was carried to such fearful extreme, phlebotomy was a most lucrative operation and the source of considerable income to many. In the Stamford *Mercury* for March 28, 1716, occurs the following interesting item: "Whereas the majority of apothecaries in Boston have agreed to pull down the price of bleeding to sixpence, let these certify that Mr. Clark, apothecary, will bleed anybody at his shop *gratis*."

Very truly yours,
CHARLES G. CUMSTON, M.D.

## RECENT DEATHS.

GEORGE CANNING HOWARD, M.D., M.M.S.S., retired, died in North Attleborough, March 19, 1911, aged seventy years.

DR. EDWARD PATRICK STANLEY HART, of Jersey City, N. J., died from pneumonia on April 9, at the age of thirty-seven years. He was graduated from the Long Island College Hospital, Brooklyn, in 1897, and for some time had been assistant visiting surgeon to St. Francis' Hospital.

DR. CHARLES A. OLIVER, who died last week at Philadelphia, was born in Cincinnati in 1854. He had practiced ophthalmology in Philadelphia for many years.

## Address.

# MEN, MANNERS AND MEDICINE.*

BY ROBERT M. GREEN, M.D., BOSTON.

OVER the beautiful iron gates that lead from the quadrangle into the gardens of New College, Oxford, twined with ivy of immemorial generations, is a scroll bearing still legibly the words, "Maners Makyth Man." This legend is the motto of Bishop William of Wykeham, founder of New College and of the celebrated Winchester School that bears his name, the oldest public school for boys in England. Apart from their pleasant medieval alliteration, the words are attractive as suggesting that the good bishop was a wise observer of "the ways and works of men," and realized how large a part is played by manners in the expression and determination of character. If, as Matthew Arnold says, "conduct is nine tenths of life," surely manners are nine tenths of conduct; and if for "manners" we read "*mores*," which probably was in Wykeham's mind, or at least in his subconsciousness, we give the motto the ethical connotation demanded by moralists and others to whom the suggestion of manners savors too superficially of the drawing-room. "Maners Makyth Man": decidedly the phrase is attractive, and the open gate over which you read it in the sunshine of an August afternoon is inviting, too. Let us enter, if not to grow in wisdom, at least to explore the garden and consider what fashion of man might arise from the manners and environment which here prevail.

This William of Wykeham, who founded the college, must have been a lover of nature as well as of boys and men, for both here and at his school in Winchester, the gardens are laid out with a lavish hand and an eye for the charms of perspective. The garden at New College extends as far as the old city walls of Oxford, which still form two of its boundaries, and whose gray flanks are an ideal background for the flaming phlox and the more delicate roses, which in England bloom till the snow flies. Though it has flowers here and there, the garden is not really a garden in our restricted sense, but an enclosed place, half meadow and half park, pleasantly diversified, with noble elms and rolling slopes, and some level lawn to suggest the desirable limitation and order of civilization. From the foot of one of the old crumbling round towers of the wall, preserved in an eternal luxuriance of ivy, one can look back through a vista of trees and shrubs to the college, whose dormitories and chapel and great hall stand clustered in academic dignity between the secluded garden and the world without.

It is such scenes, familiar in the every-day life of students in New College, as at other English universities, that have played their unconscious part in molding the manners and habits of thought of the men educated among them. In the great Memorial Hall of our own Harvard is the motto *Abeunt studia in mores*, "A man's studies pass into his manners of life"; and the phrase recurs to us as we meditate in Wykeham's garden. If "maners makyth man," "studies makyth maners"; and the studies pursued in such a place, which pass into and inspire the manners and thoughts of the college generations, must have a character which imparts something distinctive to the personality of those thus trained. Nor does this apply solely to academic scholars, but to all the liberal professions as well, and to none more than to medicine. It is a truism that physicians, more than any other class, as a result of their training and associations, come to view life very differently from any one else, so differently that they often grow into an almost clannish isolation from the rest of the human society which they study and serve. Moreover, the doctors of one country differ from those of another, and one cannot help feeling that it is something in the local environment of their education that makes them what they are. From the seclusion of Wykeham's garden it is diverting to reflect on some of these circumstances in other countries than our own.

In England a majority of the men who study medicine have come from schools and colleges like Wykeham's. New College itself has supplied its quota of more and less distinguished members of the profession. In such institutions they have studied Latin, Greek and mathematics, after the fashion which for centuries has proved successful in producing good and able men. They have learned, too, the gentle and vanishing art of orthography, can write a good letter and are intelligently familiar with literature. They have not neglected the sciences, nor have they pursued them to the exclusion of the arts. They have learned to think, and have learned it not solely in class-rooms, but out-of-doors. Not a few of the world's greatest scientific ideas have been conceived in gardens.

From such invironments, these men have gone to medical schools in the large cities, where specialized knowledge was superimposed on a well-laid general foundation. Yet even here, the humanities are not forgotten. Every school has its general library and, even in London, its garden, where the traditions and habits of college life may be maintained. When a man has obtained his medical degree, he serves as resident in some one of the larger or smaller hospitals. These, too, have their chapels and gardens, their opportunities for remaining in contact with other aspects of life. Some of these hospitals, especially in the smaller towns, are particularly fortunate in their surroundings. At Canterbury is one, the Kent and Canterbury Hospital, built on the grounds of an ancient priory, from the gate of whose garden one may catch fascinating glimpses of cloisters and old monastic ruins. Many of the English hospitals, indeed, are developed from old religious infirmaries and almshouses. One such, at Warwick, the Leicester Hospital, is reputed the oldest and most famous on its original

* Read at the annual meeting of the Boston Society for Medical Improvement, Jan. 30, 1911.

foundation, and its cloistered quadrangle is a spot to invite meditations on many topics, on men as well as on medicine. Even the modern hospitals have such stimulative environment as well. Behind the Royal Victorian Tuberculosis Sanatorium at Ventnor, on the Isle of Wight, is a steep wooded park, through which a glorious waterfall "leaps in cataract after cataract to the sea." Such a spot, overlooking the white chalk cliffs of the Channel, should have educative and therapeutic value beyond mere climate.

These, then, are some of the details of environment which determine the manners, the habits and customs of thought, the cultural background of physicians in England. As one meets them, older and younger, they are men of generalized education, not solely concerned with science or with money-getting, keen in the pursuit of the problems of their profession, but with a broad sympathy for other human interests as well. Their manners are something those of the scholar as well as of the physician, and medicine to them is more than a means of livelihood or an abstract science. And this humanistic habit, these manners that make the man, they have acquired from the nature and surroundings of their preliminary and professional training.

Now, in Germany, very different ideals and methods of education prevail from those that exist in England. Here the prospective physician spends his earlier youth at the gymnasium, a combination of high school and college, following a curriculum which, though not devoid of language and letters, is much more business-like and scientific in system. In his university, the spirit of militarism, which dominates the land, gets possession of him. Everything is system, method, organization towards a definite end, and that end usually a pretty materialistic one. Each student aspires to make his fighting corps, and in the process is highly interested in fighting his duels and drinking his beer. To be sure, German students are great athletes, but rather in gymnastics than in games. They are intensely fond of tramping and climbing, too, but their interest is rather in getting somewhere than in what they may see on the way. Of reading, of general culture, one seems to see and hear little. Those things are considered the business of scholars, and are relegated to them. In short, the temper of education in Germany is strenuous, materialistic, systematic, bent on accomplishment, with little heed for incidentals.

When a man, thus prepared, passes in Germany to the medical department of his university and later to his hospital, he follows the same method and spirit. He has before him a wealth of material, and he devours it with the same businesslike energy. Between him and his patients there seems seldom to be the same comradeship and sympathy that one notes in English and American physicians. He looks on them as cases, without much human interest. His medical and hospital life, too, are much such as had gone before. His amusements and diversions are of the same nature. *"Abeunt studia in mores."*

In fairness it ought to be said that many of the universities and hospitals have great natural beauty of environment. Most beautiful and typical of all is, of course, Heidelberg, which, to Americans at least, stands as the representative of all that is most fascinating and romantic in German university life. Here the glorious old castle, bowered among the wooded slopes that rise majestically from the river, commands the splendid valley of the Neckar and dominates the beauty and character of the scene. The university itself is in the little town that straggles at the foot of the hills. It is a famous place, comparable in position if not superior in size and importance to Oxford. But its buildings are dingy, it lacks in elegance and refinement, its atmosphere is of business rather than of leisured culture. The hospitals are near the university and nearer still to the river, and their character is essentially the same. Great possibilities in natural environment and beauty they have, but these are not made a part of the institutions. Doubtless those who work there feel their charm, but they feel it in a different way. The German esteems culture and natural beauty as they contribute to his own pleasure or advancement, the Englishman as their companionship leads him to closer sympathy and companionship with mankind in all times, past and present.

Incidentally, it should be said, that out of the Middle Ages there have survived, in Germany as in England, certain hospitals on ancient foundations which seem to retain something of a more picturesque character. But these are now almshouses or are not used for medical purposes at all. They are not institutions that make part of the working medical world. One of the most picturesque, at Nürnberg, built on a bridge spanning the river, is now left stranded in the mart of a busy mercantile city. Another, at Rothenburg, shares still the charm of that enchanted town. It is a round, redoubt-like building, incorporated in the ancient walls and fortifications, but within it is a fascinating court, with fine old trees, that might once have been a fit place for lounging and meditation. It is now, however, entirely disused. Such institutions, however, are but random survivals. The medical profession in Germany to-day is essentially a new creation, a result of the new imperialism that has made the people a nation. Though the inheritor of a great past, it does not strike its roots into that past. Its spirit is modern, intensive, practical. It achieves new things, it does not concern itself with incorporating the old into its new fabric. As a result, its achievements are splendid, but their temper and that of the men who accomplish them is different from that of our own country and of England. In Germany, as indeed everywhere, the studies, the interests, of the profession, pass into the character of its members. Training and environment work out the same law and illustrate the universality of the wise old bishop's apophthegm, "Maners Makyth Man."

Of the character of medical education and students in France, it is harder to form an esti-

mate, for the reason that the factors determining it are more subtle and difficult of analysis. In a general way, of course, the Lycée there corresponds to the German university, and to it the medical student comes from his previous preparation with the distinctive intellectual habits of his race. The educated Frenchman is above all a theorist, a thinker, and he can think, and through the lucid medium of his language express himself, more clearly and more logically perhaps than any one else. This trait, based probably on habits of study, passes, too, into the professional manners and customs of the French physician. With him everything is precise, definite, finished; the problem of a case or of a piece of research is clearly seen, the conclusion neatly drawn. The practice of his profession or the pursuit of his scientific investigation affords him something the pleasure of the mathematician. Let it not be inferred that he is not practical as well. Indeed, some of the most brilliant and useful of scientific discoveries are due to French genius. But these seem to have been made by intellectual penetrativeness more than by the patient empiricism of the German.

Of French schools and hospitals as expressive of professional character, there is perhaps less to say than is the case in England and in Germany. They are architectually beautiful always, for the Frenchman is first and always an esthete, and their artistic beauty must react as an environmental determinant. But it is beauty of an artificial rather than of a naturalistic sort. One French institution perhaps deserves comment in this connection,—the Morgue of Paris,—where, behind plate-glass and an exquisitely wrought brass railing, the unknown flotsam and jetsam of the great city used daily to be exposed, propped in chairs, a ghastly parody of some display in a boulevard shop-window. This pathologic parade, now happily stopped, seemed a surprising contradiction in the French character, whose nobler attitude towards the mystery of death is exemplified by the Monument to the Dead in Père Lachaise Cemetery nearby. With the French, to feel is to express, and the publicity which they give to things which among other peoples exist but are secluded is but another evidence that manners oft proclaim the man.

From the starting-point of our meditations it has been a far excursion through foreign fields; but we can return perhaps to Wykeham's sunny garden with a more illumined realization of the fundamental truth of his simple motto. After all, it is the habitual racial environment of a people which passes into their manners and determines what fashion of men they shall be. In our comparisons of different countries, their traits and customs, their men and their physicians, we have intended nothing invidious. In each, the local habit is its own best reason for being, and best fits those who wear it for their particular service. Nor have we purposed any uncomplimentary comparison with our own country. In America we were fortunate in starting afresh. We brought with us many aspects of environment from England and English university, and with these have incorporated from time to time the better elements from other lands. Our early university training resembled that of English colleges more than it does to-day, and in our older colleges, there were associations and suggestions like those that throng Wykeham's garden at Oxford.

The sentiment of an Englishman to his college, and the charm which creates it, are much like those expressed in the seldom heard, unfortunately almost forgotten, but most beautiful stanza of "Fair Harvard."

> Thy shade is more pleasant, thy sunshine more dear,
> Than descend on less privileg'd earth:
> For the great and the good in their beautiful prime,
> Through thy precincts have musingly trod,
> As they girded their spirits and deepened the stream
> That make glad the fair city of God.

Something of this devotion, something of this loyalty, which is midway between love and patriotism, and partakes of both, is the feeling inspired by the scenes in which the English boy pursues the studies which pass into his character and determine the manners which make him a man.

Our modern system of education in America seems to have departed widely from many of these ideals, but they are still potential and are at the core of our nationalism. In medicine, as in other activities, we have developed particularly a trait which seems characteristic of our people. We have become opportunists, that is, we seize the thing that at the moment is essential to be done, and do it, usually successfully. This American faculty Kipling has described in the phrase

> "And turns a keen untroubled face
> Home to the instant need of things."

This opportunism is perhaps not a great habit of mind, but it is useful, and does not preclude higher occasional functions. It is doubtless the result of the special circumstances of our national development, and it has passed into our national character. One sees it reflected in the daily manners and habits of thought and action of students, of physicians, of men in all walks of life.

In conclusion, then, we may, perhaps, from our somewhat desultory meditations, have reached the ancient realization that there is nothing new; that Wykeham's words of six centuries ago were true centuries before he uttered them; that manners made the cave-man as surely as they make us. But it may not have been without profit, if we realize also that, for us in medicine, it is the nature of the studies we pursue, and of the surroundings in which we pursue them, that largely determine our professional manners of life and thought. These cannot be better than such as are inspired by the sunny garden of which we now take farewell.

# CLIMATIC TREATMENT OF TUBERCULOSIS.*

BY GUY HINSDALE, M.D., HOT SPRINGS, VA.,

*Secretary of the American Climatological Association; Ex-President, Pennsylvania Society for the Prevention of Tuberculosis; Fellow of the Royal Society of Medicine, etc.*

THERE are some people, especially of a skeptical or combative tendency, who refuse to admit that climate plays any important rôle in the cure of tuberculosis. One of these, who was formerly in charge of a widely known institution for the study, treatment and prevention of tuberculosis, has said: "I desire to go on record as believing that there is no therapeutic value in climate." This same physician probably owes his life to the fact that thirty years or more ago he left the city and removed to the mountains of Pennsylvania for the relief of a pulmonary disease and recovered. Such an attitude is a study for the alienists or psychologists and would hardly seem deserving of serious attention except that we hear such statements as this: "If a case of consumption cannot be cured in its home climate, it cannot be cured anywhere."

I think there is no doubt that if any in this audience were told that he is in the incipient stage of tuberculosis he would immediately take steps to familiarize himself with the line of treatment which would, before much time had elapsed, involve leaving Boston, New York or Philadelphia, as the case might be, and so live as to enjoy what air and sunshine and other atmospheric features might afford.

One reason why home climates, if such a term can be used, have grown in favor is that it has been found necessary to establish a large number of state sanatoria, or at least to seek aid for private sanatoria from some of our state legislatures. It is a matter of expediency to have such sanatoria, and legislators must be convinced that good results or, if necessary, the best results, can be obtained close at hand. We are all heartily in favor of such institutions whether we should wish to stake our chances of recovery in any of them or not.

Of course we do not claim that there is any specific climate for tuberculosis, and the long search for such climate, a search lasting for nearly two thousand years, is apparently at an end.

Now what is left to us, and what do we understand by a climatic change?

We all know that the New England climate is changeable, i. e., the meteorological conditions are constantly varying, just as they also vary in the Mississippi Valley and along the Atlantic seaboard. But the New England climate is peculiarly unstable and, as Charles Dudley Warner has said, "New England is the battleground of the weather."

We have a change of climate when we leave the hot city in summer and go a few miles into the country or to the shore. We have floating hospitals so that this climatic change may stimulate a sick child to recovery. A so-called "home climate" may work a cure or aid in a cure because we leave the climate of our homes, often too dry with furnace heat, too poorly ventilated, too damp from lack of sun, and remove to more hygienic dwellings in the same locality where sun and air and cleanliness abound.

But, to take up the principal question at issue, the first thing usually asked is whether one should go to the Adirondacks, Colorado, New Mexico, Arizona, California or elsewhere in order to get what is so frequently claimed to be the greatest climatic advantages. No one who has visited these localities can fail to be impressed with the living examples of recovery from tuberculosis. Denver, Colorado Springs and innumerable towns in southern California abound in doctors who have practically recovered from this disease and are earning a living that is the envy of their Eastern confrères.

Would they have recovered in their Eastern homes? Almost to a man they answer, "No." I have never heard of an exception. But the case is so hard to prove from such *ex parte* evidence. However, it is interesting to note Dr. H. B. Dunham's conclusion. He stated in 1904, and reaffirms it in 1911, after visiting discharged Massachusetts Sanatorium patients in the West, and after comparing Massachusetts Sanatorium statistics with those of the United States Army Sanatorium at Fort Bayard, that "the results corroborate our belief in the efficacy of residence in dry climates, but with a smaller margin in its favor than was anticipated. The proportion of people adapted for treatment in these extremes of climate must be more equal than thought possible by climatologists generally. That is to say, a small majority of the patients at Rutland would probably do better at Fort Bayard, and a large minority might do better here [at Rutland]." But no one can say positively in any given case what would have been the outcome had he chosen differently. Dr. Solly used to say "Had I been living in London to-day I'd be dead." He lived and worked for thirty years in Colorado after trying other climates, only to be disappointed in them.

We need not discuss the bearing of what to do for the poor or what to do for the rich, or the question of food or the physician's medical management; these are important and may govern the choice, but what we want is an answer to the abstract question of the influence of climate.

We believe that *a good climate*, and by that I mean better than any city can afford, is of *first importance in governing the manner of life and that it should always be afforded to patients carrying out the hygienic, dietetic treatment of all forms of tuberculosis and of many other diseases.* There are some elements of climate that have a more positive influence in hastening cure than others. The first place must be assigned to an abundance of air as nearly as possible bacteriologically and chemically pure. It goes without saying that city air is polluted by smoke and dust and all dwellings whether in the city or the country are far below the standard of purity desirable. Only

* Read at the meeting of the Boston Medical Library and Suffolk District Medical Society, Feb. 1, 1911.

on the sea or at the highest elevations can we get air really pure, but we can approximate it by living out of doors. There is a climate of the city, a suburban climate, a climate of the country, woods and plains, all differing as regards purity of air. We are all probably agreed on this point.

Next comes the subject of sunshine. We admit that good results are obtained in cloudy regions, as, for instance, in the Adirondacks and at Rutland; but there is at least no objection to sunshine, and I believe that the moral effect of bright sunny days and plenty of them is very great. Invalids always welcome the sun. We can protect ourselves from too much, if need be, and I for one believe that sunlight does a vast amount of good, and sunny regions are much to be preferred, other things being equal. That is the great asset of our western plains and mountains, and it is a real asset that counts. Of course there are exceptions. Tastes differ. Dr. Solly used to relate the story of one of his countrymen who had been sojourning in Colorado and finally returned to England. As he landed in a fog and found himself home again he exclaimed, "Thank God! I am out of that beastly sunshine." I do not suppose he intended to be irrational or ungrateful for the greatest of all natural gifts.

Now, what other climatic conditions besides pure air and abundant sunshine have we to help us? Is a cool climate or a warm climate the best? Is a dry or humid climate to be preferred? These qualities of temperature and humidity may as well be considered together. Undoubtedly for the majority of cases in the first stage the climate should be dry and the temperature comfortable — not warm enough to be relaxing, but not so cold as to be repellant and restrict exercise or out-of-door life. It is true that in special localities better results are obtained during the cold months than during the summer. This is true of the Adirondack Cottage Sanitarium in the state of New York. One reason for this is that in winter the lakes and ponds are frozen and covered with dry snow; the air is drier. It is far enough north and at a sufficient altitude to escape the alternate freezing and thawing that is experienced in New York City, where unquestionably it is less favorable for the consumptive during the cold season than during the warm months. Take Florida and South Carolina: Undoubtedly the best season there is during the winter months, as the summers are oppressively warm and wet. The winter is the dry season and the temperature is comfortable. The interior of Florida forty or fifty miles from either coast is reasonably dry. As far as Arizona and New Mexico are concerned, the summers are too hot at all the lower elevations for any invalid, but at the higher elevations, 5,000 or 6,000 or 7,000 feet, the summer heat is not oppressive. Along the southern coast of California, and at many of the resorts somewhat inland, as good results are obtained in summer as in winter, although the latter is the more fashionable season for Eastern visitors.

The southern California resorts which have been most frequented by consumptives vary greatly between themselves as regards the important question of humidity. That a place is frequented by consumptives does not prove that it is a desirable place for them. Many of them are misguided, wandering invalids, sent out from the East with little or no judgment as to their individual needs, and with no proper knowledge on the part of their medical advisers as to the humidity or local character of the places to which they are destined. A man, for instance, will go to Los Angeles. It does not take him long to find out that while the air is fairly dry from 11 A.M. to 5 P.M., it is always damp at night. Six hours out of twenty-four are dry; the remaining eighteen are decidedly damp. The physicians of Los Angeles do not claim that their climate is a suitable one for cases of tuberculosis, and usually send these cases to the interior stations, such as Monrovia, Sierra Madre, Redlands or Riverside. Many are sent to Arizona and Colorado. Experience shows that consumptives do better if they avoid the coast region. Or, if near the coast, as at Santa Barbara, they are better if they find a site at some elevation on the hillside or in the Ojai Valley or other mountain valleys beyond the reach of the morning fog and the excessive humidity at the shore. The records of the Weather Bureau show that these places on the coast or within reach of the fogs which penetrate inland have a greater humidity than Boston or New York, the mean annual absolute humidity for Santa Barbara, Los Angeles and San Diego being given at 4.20, 4.42 and 4.34 gr., more than one third more than that of New York and Boston, 3.19 gr. and 2.84 gr. The mean annual relative humidity of all these places mentioned is from 72 to 73%. But the advantage of places like Santa Barbara, San Diego, Redlands and Riverside lies in the fact that the mean annual humidity shows a remarkable variation during the twenty-four hours compared with places like Boston, New York or Philadelphia, where the daily range is much less. At Redlands, fifty miles inland from the Pacific Ocean, one of the best known stations, the hygrometer has been known to indicate in fair weather 55% at 4.30 P.M. amd 80% at 6 P.M. The relative humidity is sometimes as low as 30% for a limited time during the day, and 70 to 80% at night when the temperature is from 44° to 60° F.

It may as well be stated that the government records of humidity are quite misleading when we use them to judge of the climate of any given place. These observations are made at 8 A.M. and 8 P.M., but in the invalid's day, made up of the intervening hours, the relative humidity reaches a much lower mark than the records show. I often observe a relative humidity in Virginia of 35 or 40% at 2 P.M., and 95 or 98% at night or in the early morning, especially when dew falls after a bright, invigorating day. I think that people whether sick or well adjust themselves to these natural changes of humidity if properly clothed and constantly in the open air, but when subject to rapid changes in humidity, as in going back and forth from the excessively dry air of a

house in winter to the damp air outside, the demands upon the mucous membranes are very great and such frequent and violent changes certainly do harm to susceptible people. Such rapid variations or alternations of the humidity of the inspired air I think are as bad as would be rapid alternations of altitude involving variations of several thousand feet.

Some patients, however, seem to do better with a humidity greater than that chosen for others. If we have a low relative humidity, and at the same time a moderately low temperature, the general effect is tonic and it is beneficial in conditions of irritability of the respiratory mucous membrane; but if the temperature is very low, this may be rather irritating. We find atmospheric conditions like this from Minnesota to the Rockies and through Manitoba and Alberta.

High relative humidity with low temperature certainly favors catarrh, and we have such conditions all winter long in the region of the Great Lakes and in New York and New England. Probably the best combination is a low humidity

Sea Breeze Hospital, Coney Island, N. Y. Daily scene in winter Cribs on porch.

and a moderately cool temperature; the average tuberculosis patient makes his best gains in cold, dry weather when such conditions prevail. But of course there are exceptions, and some do better with a high relative humidity and a warm temperature; these are not numerous and probably include more of the patients in later stages when expectoration is profuse and vitality is low.

Dr. William Gordon, of Devonshire, England, has just published a book in which a close relationship in shown between the prevalence of strong rain-bearing winds and the presence of phthisis. He confined his investigations to Devonshire, covering the period 1860–1904. Special effort was made to isolate the influence of rain-bearing winds and all other concomitant factors, including social condition, meteorologic features, soil, etc. After eliminating the possible influence of each one of these elements, the conclusion seemed to the author inevitable that rainy winds increase the phthisis mortality. This influence was notable in Devonshire as well as in Wales, Scotland, Germany, Corsica, Spain and Italy. Dr. Gordon shows that the influence of soil, hitherto disputed, seems likely to be shown at least as important as Buchanan thought it to be; but the effect of altitude *per se* on the prevalence of the disease seems like to be proved relatively small, if it be not actually non-existent.[1]

The old idea about equability of temperature, at least between the temperature of midday and midnight, is not of great importance; all mountainous stations show great variations in this respect. Some variability tends to stimulate the vital activities, but in older people and those who are feeble, great variability is a disadvantage. A moderately cool or cold atmosphere tends to stimulate the appetite and thus favors nutrition.

As far as altitude is concerned, it probably has not, *per se*, any great influence; certainly to my mind not so much as we used to think. However, altitude is incidentally associated with mountain life or life on the plains, with more sun, less moisture and scattered population. We should not forget that surgical tuberculosis is always favorably influenced by a seashore residence suitably chosen.

I never shall forget the wonderful impression made on visiting the Sea Breeze Hospital for Tuberculous Children on Long Island, N. Y. Constant outdoor life in all weather worked miraculous cures after the most formidable operations for bone tuberculosis in patients whose physical condition on admission was most unpromising. All the great French sanatoria for tuberculous children are located on the seashore; and the Rhode Island Hospital maintains a branch for this class of cases on the shores of Narragansett Bay.

Our lamented Dr. Knight formulated some opinions based on his long experience. He was a keen observer and he had the great satisfaction of seeing many a patient recover after climatic treatment. He limited the age of those resorting to altitude to fifty years. In temperament he preferred the phlegmatic to the nervous, with an irritable heart, with frequent pulse and inability to resist cold; and with the latter we must be careful not to include those who show nervous irritability from *disease*, not temperament. Patients who are irritable from disease are generally benefited in high places. As regards disease, he first considered cases of early infection of the apices of the lungs with little constitutional disturbance, and, although these generally do well under most conditions, yet considerable experience assured him that more recover in high altitudes than elsewhere.

It is best to begin with low altitude in patients with more advanced disease showing some consolidation but no excavation; also when both apices or much of one lung is involved and the pulse and temperature are both over 100.

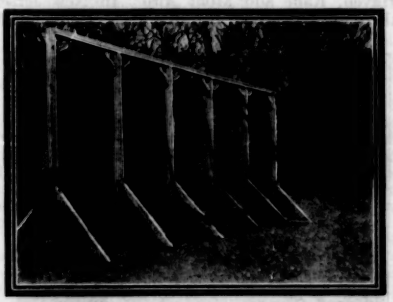
[1] William Gordon, M.D.: The Influence of Strong, Prevalent Rain-bearing Winds on the Prevalence of Phthisis. H. K. Lewis, London, 1910.

Hemorrhagic cases, early cases with hemoptysis and without much fever, are benefited by high altitudes. This accords with the latest reports from the United States Marine Hospital Sanatorium at Fort Stanton, N. Mex., altitude 6,200 feet. Dr. F. C. Smith records 56 deaths from pulmonary hemorrhage in a total of 524 patients since the hospital was opened in 1899. His conclusion is that pulmonary hemorrhage is not more frequent at high altitude than at sea level, but the results are perhaps more often serious, especially in those with impaired circulation.[2]

Patients with advanced disease, those with cavities or severe hectic symptoms, should not be sent to high altitudes. A small, quiet cavity is not a counter-indication; hectic symptoms are counter-indications. Patients in an acute condition should not be sent away.

Convalescents from pneumonia or pleurisy are usually well suited for elevated regions.

Advanced cases of tubercular laryngitis, if good local treatment and freedom from dust can be obtained, may do no worse in elevated regions than elsewhere.



In cases complicated with cardiac dilatation we cannot advise altitude; but a cardiac murmur resulting from a long past attack of endocarditis with no sign of enlargement or deranged circulation should not prevent.

Nervous derangements of the heart are usually counter-indications.

Fort Stanton is open to sailors in the merchant marine and they are transferred from the various marine hospitals to this admirable inland sanatorium. It was found that the results have been nearly three times as good in the cases which left the home stations, i. e., the local marine hospitals, without fever as in those who had a temperature of 38° C. (100.4° F) or more within two weeks of departure. The deaths in those leaving afebrile were to those leaving with fever as 22 to 59; the arrests as 19 to 7½; the apparent cures as 10 to 0. Surgeon Smith holds that the case that should be sent to a distant climate immediately upon diagnosis is exceptional and he also adds that neglect to make an early diagnosis does not warrant precipitate haste in sending the victim away when it is finally established. The psychologic moment for a climatic change is when there is a comparative quiescence of the lung process under treatment at home, when nutrition is improved and further inprovement is slow (Francine). Climatic change, however, must sometimes be made, as we will see later on, when the hoped-for stage of quiescence does not occur.

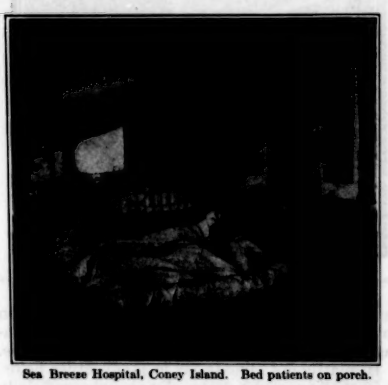
Before allowing patients with pulmonary diseases to go long distances or to make any great change to higher altitudes, some caution should be given. In the first place, patients should not make any physical exertion for two or three weeks after arrival. The air may be stimulant, there may be sights to see and many dangerous invitations given, but it is absolutely necessary that the patient should be adjusted to the new atmospheric conditions. Acclimatization is necessary to comfort and safety. In the old days it was accomplished by the slow ride in the stage coach over the plains. We cannot go back to the old methods, and, therefore, we must exercise greater caution. Financial considerations are highly important. Expenses are usually underestimated, and the want of sufficient means, the need to economize as regards the necessities, not to speak of the luxuries of life, is a dreadful handicap and should bar out many a case that succumbs for want of the very comforts he had left behind. It would be far better for such patients if they should enter some special hospital or sanatorium for consumption such as are found in most of our Eastern states.

No one should be sent away without definite and satisfactory knowledge of the place to which

Sea Breese Hospital, Coney Island. Winter amusements of children

he is sent, and without a letter of introduction to some favorably known practitioner containing a statement of the main points in the case.

In matters of climate, as in many other fields, it is the man behind the climate who will help the patient, save him from errors and indiscretions, advise him and direct him as to local surroundings and enable him so to live that his disease shall be arrested.



Some localities favorable for tuberculous patients have already been mentioned. Taking the country as a whole, we naturally look to the elevated, sparsely settled regions of Colorado, New Mexico, Wyoming, Montana, Nevada, Utah, Arizona and California. The slopes of the Rocky Mountains and the Great Basin are justly entitled to first choice, provided always that other safeguards than climate are to be had for the protection, the comfort and nutriment of the patient. Texas, especially the central and higher western portion, must be included in this great area. Life in Texas was formerly rather too rough and food and accommodations were too primitive for fastidious people, but now at places like San Antonio and El Paso these defects have been remedied. The winter climate of Texas is very agreeable except when the Texas norther descends and holds everything in an icy clasp.

[2] Public Health Reports, United States Public Health and Marine-Hospital Service, Nos. 35 and 51, by F. C. Smith, Passed Assistant Surgeon, Washington, 1910.

However, this is not altogether a disadvantage, *if not too severe.*

Florida suits some cases of phthisis. The interior of the state is sandy and the winter and spring climate is excellent. The cultivation of orange groves and the other agricultural features of the state have given many a patient a profitable occupation that he would never have found elsewhere.

Thomasville, in Georgia, sixteen miles from the Florida line, and Aiken and Camden in South Carolina, have long had a reputation for the relief of pulmonary affections. Asheville, N. C., is more elevated (2,000 feet) and is an excellent "all-the-year-round" climate. Special attention is given to tuberculous patients at this resort, and this is something that cannot be said of all the good places. In Pennsylvania suitable places are found in the Pocono Mountains, at White Haven, Kane and Mont Alto. In New Jersey there are Lakewood, Brown's Mills, Haddonfield,

Sea Breeze Hospital, Coney Island. Bed patients on porch.

Vineland and, for special cases, such as chronic fibroid phthisis, we may advise Atlantic City.

In New York there are the Adirondacks, especially the vicinity of Saranac; Liberty, in Sullivan County, where there is an excellent sanatorium. In New England there are institutions at Rutland and Sharon, Mass.; Wallum Lake, R. I.; Wallingford, Conn. But, as we have said before, the choice of a place, whether near home or at a distant point, involves all the questions of diagnosis, of temperament, of financial resources, all of which you must weigh as conscientiously as though your own life depended on it.

Of late, English physicians have been making more extended use of the higher Alpine resorts. Among these, Davos Platz, altitude 5,200 feet; San Moritz, 6,000 feet; Arosa, 6,100 feet; and Leysin, 4,712 feet, are usually chosen. Their chief characteristics are an atmosphere of dry, still, cold, rarefied air; absence of fog, few clouds and very little wind. There is, therefore, strong sunlight with a grateful warmth in the sun's rays.

In selecting cases for treatment by change of climate we must exercise as much discrimination as in applying any other remedial measure. Indeed, more caution should be used, for the patient will pass out of observation and in most cases the advice given involves the more vital consequences.

Among the numberless histories of the climatic cure I will give only one, and I think I may safely let it stand as a good example by which to let the argument rest. The history is that of a physician whom we all love and respect. It was published, together with twenty other carefully recorded histories, by that prince of clinicians, the late Dr. Alfred L. Loomis, in the *Medical Record* and formed part of a paper read before the Medical Society of the State of New York in 1879, a paper which we commend to your attention. Dr. Loomis says:

"At the age of twenty-five this patient, being of good family history, began to lose his health in the winter of 1872. His symptoms were rapidly becoming urgent; he was examined by several physicians. Extensive consolidation at the left apex was found, extending posteriorly nearly to the angle of the scapula; on the right side nothing was discovered save slight pleuritic adhesions at the apex.

"He was ordered South, but returned in the spring in no way benefited. On the contrary, night-sweating had set in, and his fever was higher. In the latter part of May he started for the Adirondacks, the ride in the stage being accomplished on an improvised bed. His condition at this time was most unpromising; he had daily fever, night sweats, profuse and purulent expectoration, had lost his appetite and was obliged constantly to have recourse to stimulants. Weight about 134 lb. He began to improve at once, his appetite returned, all his symptoms decreased in severity, and after a stay of more than three months he returned to New York weighing 146 lb. with only slight morning cough, presenting the appearance of a man in good health. A few days after his arrival in New York he had a chill, all his old symptoms returned and he was advised to leave for St. Paul, Minn., where he spent the entire winter. He did badly there; was sick the greater portion of the winter. In the spring of 1873 he again went to the Adirondacks. At this time he was in a most debilitated state, was anemic, emaciated, had daily hectic fever, constant cough and profuse purulent expectoration.

"The marked improvement did not commence at once, as it did the previous summer, and the first of September found him in a wretched condition. I then examined him for the first time and found complete consolidation of the left lung over the scapula and suprascapular space, with pleuritic thickenings and adhesions over the infraclavicular space. On coughing, bronchial râles of large and small size were heard over the consolidated portion of the lung. Over the right infraclavicular region the respiratory murmur was feeble, and on full inspiration pleuritic friction sounds were heard. I advised him to remain at St. Regis Lake during the winter, and although he was repeatedly warned that such a step would prove fatal, he followed my advice.

"From this time he began slowly to improve. Since that time he has lived in this region. At the present time his weight is 158 lb., a gain of 22 lb. since he first went to the Adirondacks in 1873, and 10 lb. more than was his weight in health. He has slight morning cough

and expectoration, his pulse is from 72 to 85 and he presents the appearance of a person in good health. In his lungs evidences still remain of the disease he has so many years combated.

"Although he has made three attempts to live in New York, at intervals of two years, each time his removal from the mountains has been followed within ten days by a chill, and a return of pneumonic symptoms — symptoms so ominous that he has become convinced that it will be necessary for him to remain in the Adirondack region for some time to come."

We all know the after history of this patient. Thank God, he is still living, — still working, — and there are thousands living to-day who owe their lives to the example which he has set them. He seized the principle of climatic treatment and adapted it to the individual.

I recently sent the following question to the deans of medical colleges in Boston, Chicago, New Orleans, Los Angeles and Montreal. I knew nothing of the views of these men on this subject except one; of course we all know that every one from California has decided views on climate. The question was:

What would you do for yourself climatically if you were told for the first time that you had incipient pulmonary tuberculosis?

Here are the answers:

In answer to your question of Dec. 26, I would say that I would treat myself as I do patients on whom I make the diagnosis of incipient pulmonary tuberculosis, that is, refer them to a local man who specializes in this disease, and ask him to look them over and refer them for climatic treatment in accordance with his knowledge of climatic conditions suitable to the individual case. Were I to start out to select a climate for myself, I would be much more influenced by the physician under whose care I would come in the new place than by the actual climate, and would probably select either Saranac Lake or Asheville, N. C., as I know and have confidence in physicians in each place. Were they to decide that I was better suited to some other climate, I would move on under their advice. If it were possible, I believe that I would undoubtedly leave Boston, had I incipient tuberculosis.

Very truly yours,
HENRY A. CHRISTIAN,
Boston.

I would strike for the wild pine woods of northern Michigan or Wisconsin and stay there.

A. R. EDWARDS,
Chicago.

In answer to your question, I may say that if I had incipient tuberculosis I should either go to Saranac or St. Agathe in Canada. I employ the open-air treatment.

F. J. SHEPHERD,
Montreal.

If I had to answer your question categorically I would say that I would ask the advice of one or two men living in my own community as to what I should do for myself climatically if I were told for the first time that I had an incipient pulmonary tuberculosis.

The practice among the profession in New Orleans is to send patients to St. Tammany Parish, in Louisiana, where the growth of piney woods is thick and ozone plentiful. When the particular case justifies, the patient is sent to the plains of Arizona or New Mexico, and, rarely, to El Paso, Tex. A few patients go to Colorado.

ISADORE DYER,
Tulane University, New Orleans.

Perhaps I can best answer your question by telling you what I did when I was told this very thing fifteen years ago. Having contracted tuberculosis in New York City, I sought a better climate for an outdoor life, spending the first summer in the Adirondack Mountains and in November of that year going to California, where I lived for one year in the foothill region near the coast at an elevation of 1,000 feet, free from responsibility and work. After the first year I never had any return of my pulmonary tuberculosis.

I believe a change of climate is more a question of finances than anything else. If one has not the necessary means to have what is right in a different climate, his chances for a cure are much better with home treatment, but when a better climate can conveniently be added to other measures of treatment for pulmonary tuberculosis, it should be advised.

W. JARVIS BARLOW,
Los Angeles, Cal.

Dr. D. Bryson Delavan, of New York, replied as follows:

"First, I would immediately consult Dr. Edward L. Trudeau at Saranac and there try to gain an accurate knowledge of the particular type of the disease which my case represented and of the general hygienic and therapeutic measures which would best meet its conditions. Secondly, if the Adirondack region proved suitable, I would remain there; if not, I would try to find another climate best adapted to my case.

"The above answer is meant to imply that the same locality may not be alike beneficial in all cases of tuberculosis. Some discrimination must be used in the selection of a place both with reference to the climate itself and also to the special conditions present at the place. However good a climate may be, it is absolutely essential that the patient be where he can secure medical advice of a high order. The truth of this proposition is proved by the fact that large numbers of patients under good medical advice make successful recoveries at home.

"My preference for the Adirondacks is based upon the fact that the region affords, first, a pre-eminently good consultant and, second, an excellent climate for the purpose within easy reach of home. It thus illustrates well the general idea which I have in mind. In dealing with the subject, there is something to be said upon the disadvantages of a climate which offers too sharp contrasts with that in which the patient must ultimately live, although in many cases the beneficial results of the clear cold atmosphere of high altitudes are apparent.

"Reviewing the matter in general, altitude seems to occupy an important place in the climatology of tuberculosis. Given an elevation of several thousand feet above the sea, surroundings suited to the case in hand and highly skilled medical supervision, the conditions at the present stage of our knowledge of the subject would seem to have been fully met.

"I am well aware of the value of certain seaside climates both in this country and abroad. On the whole, however, they are inferior to localities which are high and somewhat dry. Much might be said about the undesirability of the surroundings often met with at some of the most widely advertised sanitaria, especially of the German type, where the fact of invalidism is kept constantly before the mind of the patient. To me this would be an important objection."

It is no easy matter to combine the climatic cure with all the accessory features necessary to get the best results. We are always learning by the experience of others, and the difficulties encountered, even at the present day, are well illustrated by the experience of our Navy Department in furnishing this method of treatment for tuberculous sailors. Some years ago the Surgeon-General of the United States Navy, on account of the increasing number of tuberculous cases arising in the service, established a camp at Pensacola, Fla., but for several reasons it was decided to select another site. The Surgeon-General reported in 1907 on this matter as follows:

Extract from report of the Surgeon-General, United States Navy, 1907.

"The ideal location for a tuberculosis sanatorium should meet the following requirements:

"(1) Altitude, from 2,000 to 6,000 feet.

"(2) A maximum amount of sunshine.

"(3) A maximum amount of dryness.

"(4) Temperature condition without great extremes, but with variability rather than equability.

"A combination of the above-mentioned conditions will give a climate in which the consumptive can live out of doors the maximum amount of time, day and night, during the entire year, which, above all, is the great consideration. These conditions were found admirably combined at the site selected in Colorado.

"To the successful conduct of a sanatorium for tubercular cases there are other features almost as necessary as a favorable climate, to wit, nearness to a base of supplies, convenient transportation facilities, abundant water supply, and, but not least, a variety of provisions for the amusement and diversion of the patients. These must be supplied as a necessary part of the equipment of the sanatorium, to offset the otherwise inevitable nostalgia and discouragement to which the consumptive is subject, and which are two of the most potent causes of lack of improvement, and without doubt two of the most difficult accompaniments of tuberculosis to successfully combat.

"New Fort Lyon is far superior in every way to all the other available places inspected, and is excellently adapted to the purpose in view. It has an altitude of 3,800 feet above the sea level and is situated on the north bank of the Arkansas River, five miles from the town of West Las Animas, on the Atchison, Topeka & Santa Fé Railroad, which passes within one mile of the reservation. The nearest spur of the Rocky Mountains is about one hundred miles distant.

"The climate is mild and dry, with a maximum supply of sunshine and a minimum number of cloudy days, comparing favorably with both Fort Stanton and Fort Bayard, N. Mex. The summers are a little cooler, the winters a little colder, the amount of rainfall, as shown by observation, a little less, and the extent of sunshine equal to that enjoyed by the above-named places, being in the neighborhood of 80 to 85% annually. In the summer the mornings and nights are bracing, and even at midday the heat is never exhausting. The winter climate is so satisfactory that in years past the Indians for hundreds of miles around always wintered in this valley. The average rainfall is eleven inches, which constitutes a very dry climate, and snow falls infrequently and is seldom more than three inches in depth and disappears quickly."

But in a recent letter from Surgeon-General Stokes I am informed:

"While the patients appear to do well at our sanatorium, in my opinion it is too remotely placed, it has not been found to have the climatic features the place promised, and, from an economical standpoint, it is enormously expensive for maintenance and general unkeep of the plant. Dust storms are frequent at most seasons, and the patients show ill-effects from exposure to these influences. In the winter time paralyzing blizzards have gripped the locality. Our medical officers have done wonderful work in building up the plant, which is fast approaching a garden spot in the desert."

To sum up this matter, I find myself firm in the belief that for the majority of incipient cases, where the patient can well afford it, life in a selected locality in the West offers the best prospect of cure; but that for eastern patients a period of training in an eastern sanatorium is highly desirable, — the first and most important stage in beginning any climatic treatment. I believe that dryness, sunshine and altitude are features of the best climate, but that they decidedly disagree with some patients when presented in extreme doses as in some of our southwestern resorts. I agree with Dr. Dunham as expressed in a letter to me:

"Given simple pulmonary tuberculosis (not far advanced), somewhat over 60% of such cases will do better and live longer in the West than they would in the East, supposing every other consideration to be equal; also that nearly 40% of the total will do better and live longer in the East than in the West, similar conditions prevailing in both places. Of course those comprising this latter 40% in the East may not do quite as well proportionately as those of the 60% in the West, but in the East they will be doing the best that they can, and a small majority (of the 40%) can be cured under eastern conditions that would probably fail utterly in the West. In other words, I believe that conditions other than money, nostalgia, etc., should enter into the question of cases of tuberculosis being treated and remaining West or East.

"Doubtless every patient who is able to afford it easily should try the West; the first and essential part of the western trial being a period of regulated régime in the East."

## Discussion.

### Remarks by E. O. Otis, M.D.

The oscillations of opinion and practice regarding the value and place of climate in the treatment of tuberculosis seem to me to be quite analogous to the varying opinions which have been held regarding the value of tuberculin. Both have had their apogee and perigee, their day of ascendency and their day of decline. There was a time, and for many years, when climate was considered the essential factor in any attempt to treat tuberculosis successfully. For example, at one time almost every well-to-do patient in this region who was able to take the journey was advised to go to Colorado, and Colorado Springs may be said to have been largely founded by consumptives, and supported by them, and very many cures were

attained even when the patients were in a more or less advanced stage, as most of them were, who were sent away. Now the pendulum has swung so far the other way that it seems almost archaic to discuss the subject of climate in relation to the treatment of tuberculosis. With many phthisio-therapeutists, perhaps with the majority, climatic treatment, in the sense in which it has been so well described this evening, is considered of little or no importance. Wherever, they say, pure air can be obtained, together with skilled supervision, there tuberculosis can be successfully treated.

"I can cure tuberculosis in any climate," Dettweiler once told me, as we were riding up to his sanatorium at Falkenstein, which was situated in a very indifferent climate. Experience has, indeed, shown that this is true; nevertheless it is an indubitable fact, and attested by a large amount of accumulated evidence extending over many years, and by the experience of such authorities as Williams, Knight, Solly, Bonney, McGahan and many others, that in the climate of many regions, particularly that of the Rocky Mountains and the great Southwest, at least certain consumptives do better and obtain an arrest of their disease which would be doubtful, if not impossible, in the so-called unfavorable climates. No one can read the cases cited by Bonney in his book on tuberculosis without the conviction that the climate of Colorado was an essential, if not *the* essential, factor in the favorable results he obtained in many of his cases. I recall cases which I believe would have never regained and maintained their health in the climate of this latitude. Granted, again, that the "cure" can be successfully carried out in any climate where the air is pure, one must admit that it can be effected with far more comfort and greater contentment in a favorable climate under constantly sunny skies than in the harsh changeable climate of northern latitudes.

Undoubtedly too much was expected of climate *per se*, just as in the case of tuberculin, and disappointment was bound to be the result in both cases. Again, much discredit was brought upon climatic treatment by what I should call the "consumptive tramp," who moved from resort to resort, never remaining long enough in one place to make the cure, or obtain any successful results.

Another cause in the lack of success in climatic treatment was the failure to appreciate the importance of constant skilled medical supervision. The tuberculous individual too often thought, and perhaps his physician did also, that if he only resided in the favorable climatic resort he could manage himself and do about as he pleased. Hence, many failures were bound to ensue. What, in my opinion, can be gained from a favorable climate, besides the first great essential of pure air, is

1. An increased amount of sunlight. "If sunlight is good at all," said Dr. Knight, "why isn't it better to have twenty-five or more days of it per month than to have ten or twelve or less?"

2. A low relative humidity — dryness of the air, which I have always felt was a valuable factor, on account, as has been observed, of its anti-catarrhal effects. Again, a moderately low, or low, temperature seems to be the most favorable for the average tuberculous individual, for it is a common observation that patients gain most in cold, dry weather. Here, however, there must be an individualization of the patient. Some find cold weather quite unbearable and suffer much from it. I recall the case of a patient who found the cold weather of Liberty, N. Y., most uncomfortable, but obtained comfort and equal benefit in the milder latitude of Aiken, S. C. As to altitude, as illustrated by such localities as Denver, Colorado Springs and others, we have no sufficient proof that, *per se*, altitude possesses any favorable effect other than the greater purity of the air and increased diathermacy and the general stimulating influence on metabolism, which influences are in themselves of great value; only, of course, it is to be remembered that not all cases are suitable for the climate of altitude.

In making a choice of climate for any case, all the individual conditions must be considered — the temperament, character, age, intelligence, pecuniary and domestic conditions and the general physical condition and local state of the lungs. In times past too many patients have been sent away, or have gone away, simply to die.

Again, it is presupposed that wherever the tuberculous individual goes, he is to be under the care and constant supervision of a physician skilled in the treatment of the disease. The majority of consumptives will always have to be treated in a climate near their homes, either in a sanatorium or at home. But for certain cases, and such as are well-to-do, I believe that climate still has an important place in the treatment of tuberculosis. There was no wiser or more experienced physician in the treatment of tuberculosis than the late lamented Dr. Knight, and I may be permitted in conclusion to quote a sentence or two from a paper of his upon "Climate as a Factor in the Treatment of Tuberculosis," which he read before the National Tuberculosis Association, and in which conservative opinion, based upon an extended and large experience, I heartily concur.

"There is no specific climate," he says, "any more than there is a specific medicine, for tuberculosis, but there is no ground for supposing that a tuberculous patient is exempt from the effects of weather conditions upon the individual in health; and if we admit that weather conditions have any effect, local or general, on the individual in health, then we must admit the possibility of utilizing this effect in treating morbid conditions of the body, tuberculosis included, and we must compare the possible effects of these elements as we find them at home, and as they may be found elsewhere, both upon the organs affected and upon the individual." . . . And, concluding, he says, "My own experience, both before and since the value of modern hygienic-dietetic treatment has been so generally recognized, has led me to continue in the belief that much is to be gained by the judicious selection of a patient's climate, or weather conditions, and we do not do our patients justice unless we consider the possible advantage of change when that is practicable."

REMARKS BY VINCENT Y. BOWDITCH, M.D.

Dr. Hinsdale has done well to come to us here, in the heart and home, as it were, of the advocates of home treatment for consumptives. His rich experience should help us to view the whole question with unprejudiced eyes and enable us to come to the *juste milieu* in our attitude of mind which is so desirable in all matters of discussion.

In spite of the fact that for the last twenty years I have been urging the necessity of establishing institutions near our homes, not only for the cure of incipient cases, but for the care of far-advanced, I have never been able to place myself in the ranks of those who, knowing how much more we can do near our homes than was thought possible two decades ago, believe, therefore, that every case of tuberculosis can be treated as well in New England as in distant climates. This has always seemed to me an extremist's view and one which is not in accordance with the results of my own experience.

Numerous examples of this fact come without effort

to my memory. Especially I recall one young man who was under my care for many months at the Rutland State Sanatorium. He was the despair of us all, for, in spite of closest care and adherence to accepted methods of treatment, he slowly and steadily lost ground until finally, quite discouraged, he decided to go to Colorado. He began almost immediately to improve there, held a position of trust in his profession soon afterwards, and returned for a visit two or three years later, the picture of health, the disease having been entirely arrested; and at last accounts he was a busy practitioner in Colorado and entirely convinced that it was the place for him.

Another case, a woman under my care at the Sharon Sanatorium years ago, steadily lost ground, but after several months finally left for Colorado Springs where she soon began to improve and lead an active life. An attempt to return was followed twice by a recurrence of symptoms, and a permanent residence in Colorado was then decided upon. She is now living there, earning her living in some light employment, the disease being quiescent, although not cured. Had she decided to remain here to fight out the battle, I cannot believe she would be alive now.

I could cite similar cases where I have tried to accomplish the desired result in New England, finally advising another climate with success. That the reverse may be the case is also quite true. I have had patients who, having gone to higher and more western regions, have returned to New England with consequent improvement in their symptoms. For this reason it is incomprehensible to me how the argument is used that because many patients undoubtedly improve and get well in some cases by using hygienic measures at home, all can follow the same course with equally good results without change. We must all recognize the usual tonic effect upon ourselves of a change to a mountainous region or even in going down to the sea. If, then, this is felt when in comparative health, why should we deny similar influences to our patients? It is a scientific fact, moreover, that high altitudes cause distinct circulatory changes and even alteration in the blood itself. As to the good or bad effect of such changes, that is another question involving the skill and judgment of the adviser, but it is folly, in my opinion, to say that there is no possible use in sending a patient away if he fails to improve near at home. It is a matter of experiment to find out what will best agree with any individual. Every case must be considered by itself. We may find that a certain climate has a beneficial effect upon ninety-nine cases out of a hundred; and for some inexplicable reason the hundredth, one of similar nature, will need quite different treatment. This is a point which should be always explained to a patient lest he go blindly forward adhering to one inflexible rule even when the first experiment has not been a success.

I am speaking now, of course, of suitable cases, that is, in which there is hope of cure. I cannot speak too strongly against the haphazard custom, now happily growing less frequent, it seems to me, of sending far-advanced cases to distant climates, especially where lack of funds deprives one of the essentials of life. Nothing can be more pitiable than the victims of such treatment. I remember well in a trip to California six or eight years ago that a man was found in the lavatory where he had died from exhaustion in an advanced stage of the disease on his way to seek health; and upon my return I helped to take care of a poor fellow just able to be taken back across the continent to his home which he never should have left. A few instances of this sort in one's experience, added to the urgent expostulation of the western physicians, are enough to convince one of the folly of such procedures.

I should much regret it if from my remarks it should be inferred that I believe less than formerly in sanatorium treatment near our homes. In an experience of twenty years my enthusiasm for it has only become more keen, even while recognizing its limitations. I only wish to emphasize the fact that in my experience there are many patients who will do better by making an entire change of climate provided the proper mental, physical and financial conditions are present.

Upon the salient points of Dr. Hinsdale's paper I am sure we agree.

## "COMMON COLDS."

BY JAMES A. HONEIJ, M.D.,

*Secretary of the Committee on Prevention of Disease, Boston Chamber of Commerce.*

THE present paper is the result of an investigation of the prevalence of common colds and the economic loss due to them, together with a study of the various types of colds, sources of infection, the vocations most affected and other facts of more or less interest and importance.

An attempt was made to estimate the number of "common colds" occurring in Boston for the period of six months from December, 1909, until June, 1910. This was done because it was believed that, apart from the medical importance, the economic loss due to common colds was greater than the average person realized. The investigation was started in the beginning of the last summer by having printed 15,000 cards like the form outlined here.

The information desired was the age, sex and occupation, whether the individual had had a cold during the last six months, and at what time and of what duration, whether he was absent from work, and, if so, for how long a period. Regarding the type of cold, whether head, throat, larynx or chest, although considered important, was expected to be only the patient's opinion, not an accurate diagnosis. Opinion, not scientific certainty, was also our hope concerning the source of infection or the manner in which the person contracted the cold.

The answer to the foregoing questions furnished the committee with sufficient facts to draw the conclusion that common colds are extremely prevalent and costly and that they are in all likelihood due to a common germ infection.

It is a matter of common observation that an individual in a household, or an employee closely associated with other employees in a single room and suffering from a cold, will, in a short space of time, in fact, often before the lapse of a week, infect all the members of his household or his companions in the workroom where he is employed. The popular idea is that colds like this are more often due to draughts of air or to the winter cold. In fact, so common is the idea that colds are due to cold air that a great proportion of people are inclined to exclude pure air and breathe impure, overdried, overheated air which depresses vitality and injures the surface membrane of the whole respiratory tract. Physicians

have found that the same laws of hygiene which tend to prevent tuberculosis also aid in preventing common colds. Members of Arctic expeditions have repeatedly recorded the fact that while exposed to great cold in polar regions they never have "colds." Only on returning to civilization and indoor life do "common colds" attack them. General Sherman noticed the same freedom from "colds" in his famous march to the sea. When his men were living constantly outdoors, and sleeping on the ground, they had no colds. But as soon as they touched civilization again colds appeared. Patients suffering from tuberculosis who naturally would seem more susceptible to changes and draughts of air are cured by sleeping with their windows open. Many cases in which a cough has been the prominent symptom before treatment have ceased to cough after being treated with fresh air. Pneumonia patients who at one time were protected from the air because of the supposed danger are now treated in the open air. Dr. Neff, of Philadelphia, makes the following statement in a circular issued by the Department of Health of which he is director: "Ventilation is the keynote of prevention from pneumonia, whether in office, public building, sitting room or bedroom. Day and night pure air should be breathed. The old superstition that the breathing of night air is conducive to disease has been eliminated from the minds of nearly all by public education, with the exception of a few of our foreign population, who still believe that some diseases are spread by the breathing of night air. As a matter of fact, the night air is purer than the day air, as there is less black smoke belching from chimney stacks and locomotives, and less dust in the air, owing to reduced street traffic, so windows should be opened both top and bottom in every sleeping room." We are, of course, here speaking of the acute infection of the membrane of the whole respiratory tract by bacteria.

Another popular idea and one which the committee hopes to disprove is that colds are due to insufficient clothing, to low or to thin shoes, to changes from hot to cold temperatures, or vice versa.

The statement so often made that an individual is subject to colds may well mean in many cases that the sufferer has not entirely freed himself from the original infection, or has subjected himself again and again to the impure air of his house or office, or has reinfected himself from another member of his family or from one of his fellow-workers before the cycle of infection has run out. In such cases the consequences frequently have been severe, if not serious. A cold may progress from the nose to the throat and lungs, and pneumonia and other serious diseases are apt to result. Acute inflammation of the inner ear and of the bony cavities of the forehead and cheek bone often results from a "common cold" and proves oftentimes a stubborn, serious and expensive malady.

Many cases of latent or healed consumption are in all probability "lighted up" into serious activity of the disease process by a common cold. The kidneys and the heart are now and then seriously affected by forms whose entrance by the throat and nose is marked by a "common cold."

Apart from the desire of the committee to obtain such information as would show that common colds are due to an infection, they hoped to show the enormous loss which must be associated with this common disease and so to interest employers to take steps towards lessening the spread of common colds, with their attending inconvenience, suffering and loss of time and money. If employers stopped to consider the possible economic loss in a business establishment employing thousands of persons if a serious epidemic of common colds breaks out, it would possibly mean that much better ventilation and better hygienic conditions would be given to employees and that every other means would be taken to make impossible the outbreak of such an epidemic.

### THE RESULT.

Of the 15,000 cards sent out, 4,230 were returned as follows: 1,633 cards were answered as positive cases, 1,318 cards were answered as negative cases, 36 cards were incompletely answered and 1,181 cards were returned not used, 10,000 were not returned. We have then 3,013 cards returned as either positive or negative. Figures were also obtained from the fire and police departments, from prisons, hospitals, factories and departments stores without the use of cards. From these sources 2,212 positive cases were reported out of approximately 3,500 persons, which, added to the 1,633 positive cards, makes a total of 3,845 individuals who have had colds during some time of the period studied, that is, from December to June. If we include the persons in the family affected with colds, the total is increased to 6,591. For the purpose, however, of a more careful study we can take only the 1,633 cases of colds which were obtained by cards.

We will consider chiefly the following professions, trades and occupations: Clergymen, 41; conductors, 107; dentists, 79; educators, 98; housewives, 64; lawyers, 96; manufacturers, 46; merchants, 114; motormen, 76; nurses, 22; office occupations, 107; physicians, 100; post-office employees, 66; department store employees, 275; total, 1,291.

This does not include 342 positive cases which were grouped under miscellaneous occupations, 63 policemen, 60 firemen and 120 prisoners. Figures obtained from street laborers, students, etc., were not reliable, due to evident ignorance and lack of serious consideration. From other trades, cards were obtained, but in such small numbers that no accurate conclusions could be reached.

It has been suggested that the figures shown here are of early middle life. Students and others below the age of twenty years have a comparatively less economic value than the trades and

TABLE I.

SHOWING AGES AT WHICH MOST COLDS OCCURRED.

| | 10-20. | 20-30. | 30-40. | 40-50. | 50-60. | 60-70. |
|---|---|---|---|---|---|---|

| | 104 | 294 | 346 | 264 | 185 | 86 |
| Total, | | | | | | 1,279 |

professions represented here. It has also not been proved that individuals below the age of twenty and above sixty years suffer more from colds than individuals between the ages of twenty and sixty years of age. Ages not given for twelve others makes the total of 1,291. Firemen's and policemen's ages not obtained.

In the fourteen occupations given, we find that the month during which most colds occurred was March. Postmen, however, were an exception to this rule, their colds occurring mostly in January and May. February and April each give about the same proportion of colds and considerably less than March. Just why March should be the severest month, if we consider colds from a bacterial point of view, is difficult to explain. If we consider March a windy and a thawing month, and that the vitality of the individual is possibly lowest after a winter of indoor life and desiccated air, we may then find some clue.

With physicians, dentists and teachers there is, of course, the risk of becoming infected from their patients or scholars and of the likelihood of breathing impure, bacteria-laden air and, of course, the same predisposing causes as mentioned above.

Among 1,291 individuals, there were 568 absent from work with a total number of 3,913 days lost from work, or 6+ days per individual.

A study of the following table will aid in understanding this.

Of the number of days lost in the different occupations, merchants average 10+; motormen, 9+, lawyers, 9+, nurses, 8+, educators, 7+, department store employees, 6+, physicians, office occupations and conductors, each 6+, clergymen and postmen, each 5+, manufacturers and housewives, each 4+, and dentists only 2+days.

The figures quoted above are modified somewhat when we consider the greater independence of occupation of those near the head of the list, with the exception of motormen. The high average absence from work of merchants and lawyers is not necessarily a proof of the severity of their colds, but, as stated, is due rather to their greater independence of occupation and

TABLE II.

SHOWING THE TOTAL NUMBER OF DAYS LOST FOR EACH PROFESSION BY ABSENCE FROM WORK AND AVERAGE PER INDIVIDUAL AND APPROXIMATE INDIVIDUAL AND TOTAL MONEY LOSS. RECKONED FOR 568 INDIVIDUALS.

| | No. with colds. | No. absent. | Total number days. | Average number days. | Approximate loss per individual. | Approximate total loss. | Approximate average earning capacity for 365 days. | Average per day. |
|---|---|---|---|---|---|---|---|---|
| Clergymen, | 41 | 12 | 67 | 5.58+ | $38.24 | $458.90 | $2,500.00 | $6.84+ |
| Conductors, | 107 | 47 | 322 | 6.85+ | 11.26 | 529.30 | 600.00 | 1.64+ |
| Dentists, | 79 | 11 | 31 | 2.81+ | 11.58 | 127.39 | 1,500.00 | 4.10+ |
| Educators, | 98 | 26 | 185 | 7.11+ | 29.24 | 760.25 | 1,500.00 | 4.10+ |
| Firemen, | ? | 60 | 309 | 5.15+ | 14.09 | 845.86 | 1,000.00 | 2.73+ |
| Housewives, | 64 | 7 | 28 | 4.00+ | 6.57 | 46.02 | 600.00 | 1.64+ |
| Lawyers, | 96 | 20 | 182 | 9.1 + | 49.86 | 997.25 | 2,000.00 | 5.47+ |
| Manufacturers, | 46 | 12 | 57 | 4.75+ | 39.04 | 468.48 | 3,000.00 | 8.21+ |
| Merchants, | 114 | 24 | 260 | 1.08+ | 89.04 | 2,136.96 | 3,000.00 | 8.21+ |
| Motormen, | 76 | 41 | 379 | 9.24+ | 17.72 | 726.61 | 700.00 | 1.91+ |
| Nurses, | 22 | 4 | 32 | 8.00+ | 17.53 | 70.13 | 800.00 | 2.19+ |
| Office occupants, | 107 | 23 | 141 | 6.13+ | 50.38 | 1,158.89 | 3,000.00 | 8.21+ |
| Physicians, | 100 | 21 | 140 | 6.66+ | 36.52 | 767.11 | 2,000.00 | 5.47+ |
| Policemen,* | ? | 63 | 565 | 8.96+ | 14.74 | 928.74 | 1,200.00 | 1.64+ |
| Postmen, | 66 | 60 | 306 | 5.1 + | 13.97 | 838.34 | 1,000.00 | 2.73+ |
| Department store employees, | 275 | 137 | 909 | 6.63+ | 9.08 | 1,245.14 | 500.00 | 1.36+ |
| Total, | 1,291 | 568 | 3,913 | 6.00+ | | $12,105.37 | | $4.16+ |

Total average loss for 568 individuals is $21 + per individual for period of six months.

* Policemen when absent lose half pay only.

consequently greater length of time in which to recuperate. With motormen and nurses, who show a high percentage, their hard and tiring occupation and perhaps their greater exposure to infection may offer some explanation.

Dentists, on the other hand, show the lowest average, which perhaps can be explained in some degree by their more equable condition of occupation and the care they naturally take to prevent infection of any kind. Policemen, who are in the open air a good deal of the time, and whose occupation is relatively similar to that of postmen and firemen, are absent from work a greater number of days than either of the two latter occupations. *The large number of employees in department stores who show a serious and high percentage of absence from work, — about 50% of the total number having colds, — becomes worthy of consideration.*

The total number of individuals which we are considering, 3,485 had colds for 11,417 days. This does not include the number of days out of work. If we include the number of days absent from work, we have a total of 15,420 days of colds.

The next point to consider is the form of cold from which most individuals suffered. By far the greater number were said to be entirely head colds — about 40%; head and throat, 15%; throat colds, 12%; chest and head, 5%; head, throat, larynx and chest, about 5% and other forms in still smaller proportion.

Probably the most important point is the involvement of the throat, which is considered a sequel of a cold from the head. This is all the more important when we take note of the fact that infantile paralysis is now considered to be a possible result of infection through the nose and throat. Just how much we can depend upon the diagnosis which each individual makes of the extent of his own cold, it is difficult to estimate.

The answers regarding the source of infection, or, as we stated it on the cards, "Where and how did you get it?" are perhaps only of importance to demonstrate the prevailing opinions.

The occupation of each individual, of course, naturally furnishes the most apparent cause for his cold. Department store employees, almost without exception, blame draughts for their colds, and motormen and conductors the fact of their getting wet. The cause given by the most number of individuals in all occupations together was draughts. Infection as a cause for colds was given mostly by the professional men and educators; the percentage of the whole number was only 7. Getting wet was the next most common cause assigned. This was given in about 5% of the cases.

When we consider that 10% of the total number of persons were either physicians or dentists, it is clear that infection as a recognized cause of common colds is not yet widely accepted.

"Subject to colds" is the statement of 23% of the total of 1,633. This probably signifies poor nutrition, poor working conditions, reinfection or ignorance of the value of fresh air. It would be necessary further to investigate this large percentage to find out just what their attitude towards fresh air, draughts, etc., is, and under what conditions they are working, if we wish to make these figures of any value.

The last question we have to consider is what number of persons were infected with a cold as a result of its spread in families. Two thousand seven hundred and fifteen such persons were reported out of approximately 3,000 households. This number, added to the 1,633 positive cases, makes a total of 4,348 individuals who had colds for the period covered.

The usual stages of a common cold after the onset are congestion of the respiratory organs, with watery serum becoming mucopurulent, some fever and a general feeling of discomfort. Colds may then extend to the bronchi or lungs. "The first suspicion on the part of the patient that he has such a cold starts from an irritation or sensation in some spot, often the nasopharynx, occasionally the larynx, nose or tonsil. During the next few hours this irritation extends to neighboring regions, and this continues perhaps for a few days, but the amount of its extension varies in different cases. It may involve by direct extension the nose, the accessory sinuses, the pharynx, the larynx, the trachea and the bronchi, but it may spare any of these parts. The local appearances are in most cases less marked than the severity of the symptoms would suggest. There is an increase in redness of the mucous membrane involved, and other signs of inflammation, generally of a mild type."[1]

According to bacteriological investigations, a number of different forms of bacteria may be present, and whether these bacteria are the cause is still the question. In many colds the discharges are sterile. But this may mean only that the bacteria are not to be starved by our present methods and will not grow on one ordinary culture media. The investigations of Dr. F. C. Cobb[2] show that the interior of the nose ("*downstream*" in the air current) *is sterile* in health and often in disease, although the front of the nose (upstream in the air current) contains great variety and numbers of bacteria. It would seem probable that the fluids or surface cells of the nose must have a bactericidal power and this power must be somehow inhibited or overcome when we "catch cold." If a single specific organism were found regularly in all cases, or if this organism regularly exceeded in numbers all other forms, or, still more, if any one of these organisms when experimentally injected into the tissues produced the symptoms of a common cold, then we could definitely state its cause. These individual organisms may produce slightly different types of colds and, if so, can probably only be determined by a careful clinical study of hundreds of cases, with an especially careful microscopical study of the bacteria. There seems to be no question that infection plays as important a part in colds as it does in diphtheria or influenza.

Infectious colds must not be confused with

[1] A. Coolidge, Jr.: Boston Med. and Surg. Jour., vol. clxiii, 1910.
[2] F. C. Cobb: Transactions of the Congress of American Physicians and Surgeons, vol. viii, 1910.

colds of a vasomotor nature or chronic catarrhal conditions, or, as Dr. Coolidge states, "that of acute disorders of the nasal chambers, some may be distinguished either as due to infection and others as arising from a local irritability and vasomotor disturbance." Infectious colds are those caused by bacteria; irritation colds are those caused by the pollen of plants, draughts, acrid vapors or abnormal conditions of the membranes.

One very apparent fact derived from the literature is that many factors predispose and coexist with colds, but this is also true of a great many diseases with which we are now more careful than we are with colds, for few really deny that acute colds are contagious. Of the various theories that have been given previous to that of infection, those of Rosenthal, Seit and others may be mentioned. *Rosenthal* believes in a vasomotor change; the chilling of the surface with the contraction of peripheral capillaries, which results in a congestion of the internal organs through blood being driven from the skin surface. The theory of *Seit* differs slightly in that he thinks the vasomotor centers are excited by the sensation of a chilled skin with resultant congestion at points of least resistance. *Brown*[3] also believes in vasomotor changes, combined with the theory that the nose plays an important part, being, as it were, a respiratory filter for moist and heated air, and that there is a close relation between the functions of the skin and that of the nose. He also states that the predisposition to colds is increased when the body is first overheated or overprotected and then chilled or under protected. The turbinates, he supposes, receive the vasomotor impulses when the body becomes chilled. *Wakefield* believes that colds produce areas of suboxidation which become inflammatory foci. *Bosworth*[4] thinks that the function of heat production is involved in that after a chill a part of the body becomes inactive while another part of the body is still active. *Allen*[5] is definite in his statement that colds are due to infections by bacteria, and, after determining the predominant bacteria, treats the cold with vaccines.

*Grayson*,[6] referring to all types of acute rhinitis, says that they have a common predisposing cause, that of chronic catarrhal rhinitis. He also goes on to say that in the physically degenerate there are so many spots of enfeebled resistance that a severe chill would result in a serious effect. Excluding all mention of bacteria, he states that in a normal man with sound tissues, exposure would result in a transient congestion of the internal structures with resulting rise of temperature. This would continue only so long as to enable vascular inhibitory mechanism to reassert its control and dissipate gathering trouble.

The difficulty, however, appears to be largely in the correct diagnosis of a cold. Diphtheria, vasomotor rhinitis and hay fever are no longer called colds. With a closer and more careful study of typical colds, and with keener observation of the period of onset, there may result the finding of a specific organism which will explain the cause of the most common forms.

It does not follow that because bacteria and not draughts are probably the "cause" of colds, we should neglect the other essential facts of under-nourishment and bad hygiene. We must remember that all infections are more serious if the patient has been neglecting his health and strength. And we believe that by sensible hygienic measures we can to a large degree prevent colds, especially through a more intelligent attitude on the part of the public and a more progressive campaign on the part of the medical profession. If plenty of pure air is allowed to enter the patient's room, if he is isolated for forty-eight hours or more and not allowed to go to business, or in the case of children, to school, much time and money will be saved.

TABLE III.

SHOWING AVERAGE AND TOTAL LOSS FOR INDIVIDUAL PROFESSIONS, TRADES, ETC., FOR INEFFICIENCY DUE TO COMMON COLDS. RECKONED ON A TEN PER CENT BASIS.

| | No. with colds. | Number of days with colds. | Average loss. | Total loss. |
|---|---|---|---|---|
| Clergymen, | 41 | 338 | $5.39 | $221.19 |
| Conductors, | 107 | 398 | .61 | 65.27 |
| Dentists, | 79 | 890 | 4.60 | 364.09 |
| Educators, | 98 | 720 | 3.00 | 295.02 |
| Housewives, | 64 | 432 | 1.10 | 70.84 |
| Lawyers, | 96 | 705 | 4.01 | 385.63 |
| Manufacturers, | 46 | 320 | 5.71 | 262.72 |
| Merchants, | 114 | 817 | 5.88 | 670.75 |
| Motormen, | 76 | 190 | .47 | 36.29 |
| Nurses, | 22 | 183 | 1.38 | 40.47 |
| Office occupations, | 107 | 789 | 6.05 | 647.76 |
| Physicians, | 100 | 920 | 5.03 | 503.24 |
| Department store employees, | 275 | 1,495 | .73 | 203.32 |
| Totals, | 1,225 | 8,197 | | $3,766.59 |

There were no figures for firemen, policemen and postmen. The figures are estimated from the earning capacity as given on Table II.

Inasmuch as this investigation was undertaken to consider the infectious form of common colds, which we believe can be largely averted or prevented, I desire to call attention in conclusion to the economic loss which we suffer from this source. According to Table II, we see that the total loss for the six months was $12,105.37. This, when divided amongst the 568 individuals who were absent from work, makes an average loss per individual of $21+ for six months. (See Table II.)

If we consider the loss of efficiency or earning power due to common colds in those who do not give up work and estimate this loss at the conservative figure of 10%, we find a total loss of $3,766.59 for 1,225 individuals.

SUMMARY.

1. Over half the population have colds during the course of the six months.

2. One fifth of the population are absent from work on account of colds.

3. The average loss of time of 568 individuals was 6+days per six months.

TABLE IV.

Estimated Loss Due to Common Colds in Boston in Certain Occupations.

| | No. in Boston.* | Percentage with colds. | | No. with colds. | Average loss. | Total loss. |
|---|---|---|---|---|---|---|
| Clergymen, | 879 | 70 + | or | 614 | $5.39 | $3,309.46 |
| Dentists, | 467 | 45 + | or | 210 | 4.60 | 966.00 |
| Educators, | 3,733 | 64 + | or | 2,389 | 3.00 | 7,167.00 |
| Lawyers, | 1,311 | 64 + | or | 839 | 4.01 | 3,364.39 |
| Manufacturers, | 1,849 | 48 + | or | 887 | 5.71 | 5,064.77 |
| Merchants, | 9,867 | 57 + | or | 5,624 | 5.88 | 33,069.12 |
| Physicians, | 1,972 | 49 + | or | 966 | 5.03 | 4,858.98 |
| Department store employees, | 18,083 | 47 + | or | 8,499 | 0.73 | 6,204.27 |
| Totals, | 38,160 | | | 20,028 | | $64,003.99 |

* The figures in the first column were obtained from the Massachusetts census of 1905.

4. The average loss of money was $21 + per six months, not including individual expenditures for medical treatment, etc.

5. The total loss in six months' time was $12,105.37 for 568 individuals.

6. In addition to this there is a loss of energy, equivalent to $3 + per six months per person.

OTHER DATA.

1. The most common cold is the "head cold."

2. Most colds occur in the month of March.

3. Individuals from thirty to forty years of age suffer most from colds. Department store employees suffer most in proportion. Half of them lose time on account of colds.

CONCLUSIONS.

1. Preventive methods are essential in dealing with common colds. Better working conditions, pure air, even temperature, proper ventilation and the proper amount of humidity are important factors. Nourishment, general hygiene and proper clothing are necessary precautions as in guarding against all other disease.

2. After the onset of a cold, proper diagnosis is essential to ascertain whether the cold is infectious.

3. Individuals suffering from infectious colds should be isolated.

I desire to thank my committee for the privilege they have granted me to publish this work.

## AN ANALYSIS OF FORTY-SIX CASES OF PROSTATECTOMY.

BY LINCOLN DAVIS, M.D., BOSTON.

### Abstracts of Cases.

PERINEAL PROSTATECTOMY FOR BENIGN ENLARGEMENT.

(Continued from No. 16, p. 571.)

Case 42. J. F. F., No. 171829. E. S. Age, seventy-six years. Widower. Retired. Entered hospital Sept. 8, 1910. Service of Dr. Brooks.

*History.* — Denies venereal. Previous health good. One year ago began to have frequency, rising ten to twelve times at night. Two days ago, retention. To-day his physician unable to pass a catheter and sent him to the hospital.

*Examination.* — Well developed and nourished. One eye enucleated, result of accident. Systolic murmur. Arteries palpable, high tension pulse. Distended bladder felt half way to umbilicus. Rectal examination, prostate smooth, hard, symmetrically enlarged. Coudé catheter passed, 32 oz. of urine evacuated. Constant drainage.

*Urine* smoky, alkaline, 1011, albumen slight trace, sugar 0, sediment, numerous red cells, leucocytes and squamous cells.

*Cystoscopy.* — No note.

*Operation*, Sept. 12, 1910, spinal anesthesia, perineal prostatectomy. Large lateral lobes shelled out. No median lobe. Usual drainage.

*Pathological report.* — Glandular hypertrophy.

*Convalescence.* — Tubes and wicks out in forty-eight hours with immediate interval urination through wound. Convalescence uneventful except for severe pain in side. Pleurisy? Oct. 6, passed small amount of urine through penile urethra for first time. Sound 29 passed to bladder. Residual urine, 8 oz. Discharged to local doctor twenty-fourth day, most of urine coming through wound.

*Subsequent history.* — Nov. 21, 1910, personal examination. Has not passed a drop of urine except through sinus since leaving hospital, has poor control, urine leaking away from him by day and night. Passed 3 oz. dark turbid urine through sinus. With much difficulty a small bougie catheter was finally passed, residual 2 drams. Right epididymitis which developed after leaving the hospital. After the passage of sounds there was no further leakage from sinus. Control improved. Epididymitis subsided.

Jan. 16, 1911, perineal sinus has healed. Passes urine once an hour at night, but has no leakage. Holds urine two hours during the day, occasionally a little urine gets away from him when on his feet. Examination: Passes urine in good stream. Residual 1 dram. Urine clear. Clothes perfectly dry, no evidence of lack of control. Principal complaint is pain in side and shortness of breath.

Case 43. J. B., No. 172045. E. S. Age, eighty-eight years. Widower. Sea captain. Entered hospital Sept. 20, 1910. Service of Dr. Brooks.

*History.* — No venereal. Typhoid fever fifty years ago. Heavy cough for five weeks, shortness of breath, and edema of feet. For ten years has had difficulty in starting urination. Last summer retention requiring catheterization. During last week has been unable to void, catheterized by local doctor. Catheterization difficult and painful.

*Examination.* — Well developed and nourished. Tongue clean, mind clear. Lungs, wheezy respiration. Mitral systolic murmur. Arteries tortuous and palpable. Bladder distended half way to umbilicus. Rectal examination, prostate enlarged, firm, symmetrical.

*Urine.* — Pale, acid, 1006, albumen slight trace, sugar 0, sediment, much pus, some blood, granular casts.

*Cystoscopy.* — No note.

*Operation.* — Sept. 22, spinal anesthesia, perineal prostatectomy. Lateral lobes shelled out, no median tissue. Usual drainage.

*Pathological report.* — Glandular hypertrophy.

*Convalescence.* — Sept. 23, patient delirious, impossible to keep irrigation apparatus working. Special nurse. Sept. 24, patient irrational, temperature elevated, gets out of bed. Sept. 28, improving, taking nourishment better. Oct. 6, epididymitis. Oct. 10, bleeding started from wound. Bladder distended, catheterized and catheter tied in. Oct. 15, abscess of testicle incised with escape of pus, considerable relief. Oct. 25, beginning to pass urine through penile urethra. Still a little bleeding from wound. Nov. 2, patient much improved, walking about, no bleeding. Nov. 19, wound has gradually closed in until it leaks now almost none. Sound 28 passed to bladder. Residual urine none. Walks about quite actively. Discharged fifty-seventh day.

*Subsequent history.* — Dec. 19, 1910, telephone report from physician. Patient has perfect control during day, at night urine sometimes gets away from him. There is still a small sinus in perineum the size of a knitting needle. General condition excellent.

April 7, 1911. Physician reports that patient is in excellent condition. Sinus has healed, no leakage. Goes out daily.

CASE 44. D. S., No. 172088. W. S. Age, seventy-six years. Widower. Farmer. Entered hospital Sept. 22, 1910. Service of Dr. Balch.

*History.* — No venereal. Has been troubled with moderate frequency for several months, four or six times in day, two times at night. Last week unable to void and has been catheterized regularly by physician since.

*Examination.* — Rather shaky old man. Marked arcus senilis. Tongue, brown coat. Heart and lungs negative. By rectum prostate symmetrically enlarged, firm, moderately tender.

*Urine.* — Acid, 1014, albumen 0, sugar 0, urea 19.1 gm. in twenty-four hours.

*Operation.* — Sept. 21, 1910, anesthol, perineal prostatectomy. Two lateral lobes removed, no third lobe. On account of persistent oozing three wicks were necessary.

*Pathological report.* — Glandular hypertrophy with retention cysts.

*Convalescence.* — Good recovery from anesthetic. Posterior wick out in twenty-four hours, lateral in forty-eight hours. Uneventful recovery. Oct. 12, good control, but most of urine comes through wound. Oct. 14, discharged to Out-Patient Department, seventeenth day.

*Subsequent history.* — Out-Patient Department note, Dec. 5, 1910: No leakage from wound which is closed. Residual, 1 oz., urine cloudy. Frequency, diurnal 4–5, nocturnal 2–3. Perfect control.

CASE 45. D. H. F., No. 173841. E. S. Age, sixty years. Married. Farmer. Entered hospital Jan. 7, 1911. Service of Dr. Harrington.

*History.* — Denies venereal. No previous sickness. About two years ago began to have frequency of micturition. One year ago had retention requiring catheterization. Ever since has depended entirely on the catheter. One month ago had an abscess which broke in the perineum.

*Examination.* — Fairly developed and nourished. Systolic murmur at apex. Lungs normal. By rectum prostate moderately enlarged, elastic, symmetrical.

*Urine.* — Foul, acid, 1020, albumen 0, quantity varied from 40–50 oz. daily.

*Cystoscopy.* — Bladder slightly trabeculated, moderate lateral projection of lobes with small median bar, no stone.

*Operation,* Jan. 12, spinal anesthesia, perineal prostatectomy. Two small lateral lobes removed. Digital exploration showed median bar to amount to nothing.

*Pathological report.* — Glandular hypertrophy.

*Convalescence.* — Very little bleeding. Temperature up to 102. Patient very drowsy. Tube out in forty-eight hours, interval urination through wound. Considerable diarrhea between sixth and ninth days. Tenth day patient up and about, feels well. Temperature normal. Jan. 25, temperature 105, some cough and dyspnea. Pneumonia, two lower lobes right side, severe pain in chest. Jan. 27, seems better, more comfortable, passing good quantity of urine through penis. Pneumonia seems to be subsiding. Feb. 3, in a sudden access of delirium, jumped out of window into snow. Carried into ward in a state of collapse, reacted to stimulation. Feb. 5, signs of fluid in right chest, aspirated, pus obtained. Under cocaine tube inserted between eighth and ninth ribs in scapular line. Two quarts of pus withdrawn. Pleural cavity aspirated twice daily through tube, dressing kept air tight. Patient gradually failed, the left lung filling with edema and râles. Death occurred Feb. 12, thirty-first day.

*Autopsy* showed unexpanded right lung covered with fibrinous exudate, pleural cavity well drained. Bronchopneumonia left lung. Kidneys and bladder not remarkable. Small unhealed sinus leading to prostate, the shell of which remained with a tiny median lobule. No evidence of infection.

Cause of death purely pulmonary.

### SUPRAPUBIC PROSTATECTOMY FOR BENIGN ENLARGEMENT.

CASE 1. A. M., No. 146448. E. S. Age, fifty-nine years. Married. Shoemaker. Entered hospital Feb. 16, 1906. Service of Dr. Elliott.

*History.* — After two years of intermittent hematuria was operated in December, 1904. L. D. Suprapubic cystotomy, excision of papilloma. Hematuria recurred in eight months. Cystoscope showed an irregular prostatic contour which was regarded as malignant and thought to be cause of bleeding. Some symptoms of cystitis, but none of obstruction. By rectum, prostate felt hard and dense.

*Operation,* Feb. 19, 1906, suprapubic cystotomy. No papillomata to be seen, prostate projects moderately into bladder; considered cause of bleeding. Removed *in toto* by finger enucleation.

*Pathological report.* — Simple hypertrophy.

*Convalescence.* — Uneventful except for left-sided epididymitis. Wound closed in one month. Discharged March 28, thirty-seventh day.

*Subsequent history.* — Hematuria recurred at the end of three months and at this time the cystoscope showed tiny papillomata scattered over the whole bladder mucous membrane. There was no trouble with micturition. No residual urine. Patient refused operation. Died of the disease March 21, 1910.

CASE 4. T. R. P., No. 153656. E. S. Age, sixty-seven years. Widower. Farmer. Entered hospital July 1, 1907. Service of Dr. Brooks.

*History.* — No venereal. For six months, pain and frequency. Urinates twelve times in the day, and six at night. Some difficulty in starting, some dribbling. No retention.

*Examination.* — Residual, 3 oz., turbid. Bladder holds 13 oz. By rectum, prostate does not feel enlarged.

*Cystoscopy.* — No note.

*Operation,* July 5, suprapubic prostatectomy. Median lobe size of thumb projecting into bladder. Moder-

ate sized lateral lobes enucleated with very little bleeding. Tube drainage.

*Pathological report.* — Hypertrophy.

*Convalescence.* — July 11, tube out. July 26, normal urination, wound closed, feels well. July 28, discharged, twenty-third day.

*Subsequent history.* — Letter of Sept. 16, 1907, states "should not know I ever had any trouble; your operation was a complete success."

January, 1911, reported by a friend and neighbor, also a prostatic, as being alive and well.

CASE 5. G. E. H., No. 154026. E. S. Age, sixty-nine years. Married. Business. Entered hospital July 24, 1907. Service of Dr. Brooks.

*History.* — Litholopaxy October, 1892, at Massachusetts General Hospital. In 1902 had suprapubic cystotomy with excision of third lobe. No relief from operation. Has used catheter entirely since operation. During last year has had frequent attacks of hematuria. Has led a catheter life for fourteen years. One week ago severe attack of bleeding from the bladder. Catheterization painful and difficult.

*Examination.* — Fairly well developed and nourished. Signs of old pleurisy in left chest. Bullet wound of leg.

*Urine*, foul and bloody.

*Operation*, July 25, suprapubic prostatectomy. L. D. Prostate projected into bladder size of tennis ball. Readily shelled out. Tube drainage. Some bleeding. Gauze packing.

*Pathological report.* — Weight of tissue removed, 130 gm. Chronic cystic hypertrophy.

*Convalescence.* — Patient mildly uremic and somnolent. Aug. 12, patient passed urine for the first time in fifteen years. Patient passed fragments of calcified matter. Urination voluntary and easy. Aug. 16, discharged, twenty-second day. Wound closed.

*Subsequent history.* — Office note: General condition excellent. Wound solid. Passes large quantity of urine at night, rises four or five times, can pass 12 oz. at a time. Urine cloudy, acid, albumen slight trace. Residual, 1½ oz. Ready to go to work. Has erections. Letter from widow stating that patient died of pneumonia three months later.

CASE 6. C. W., No. 154557. Age, sixty-eight years. Married. Carpenter. Entered hospital Aug. 28, 1907. Service of Dr. Brooks.

*History.* — For past year has had frequency. Retention for three or four weeks. Catheterized himself with home-made rattan catheter.

*Examination.* — Well developed and nourished. Double inguinal hernia. Sixteen ounces of urine obtained by catheter. By rectum, firm, symmetrical, bilateral enlargement of prostate.

*Operation*, Aug. 29, suprapubic prostatectomy. Large middle lobe, whole gland enucleated entire. Considerable bleeding. Tube drainage with gauze packing.

*Pathological report.* — Chronic fibrous hypertrophy.

*Convalescence.* — Continuous and profuse bleeding for two weeks which all efforts failed to stop. Double epididymitis. Bleeding finally stopped spontaneously. Discharged Oct. 14, forth-sixth day. Wound healed. Natural urination.

*Subsequent history.* — Letter, Oct. 17, 1908, reports that he is enjoying the best of health.

CASE 8. J. F. H., No. 157351. E. S. Age, sixty-two years. Teacher. Entered hospital March, 1908. Service of Dr. Scudder.

*History.* — Gonorrhea and syphilis thirty years ago. Used to be a heavy drinker, does not drink now. For ten years has had frequent micturition and incontinence. Has worn urinal for past six months. Passes urine from fifteen to thirty times at night. Lately has been troubled with shortness of breath.

*Examination.* — Poorly developed, emaciated. Mind somewhat clouded. Arteries sclerotic; pulse, high tension. By rectum, prostate hard, firm, sclerotic. Residual urine, 18 oz.

*Urine.* — March 9: Total quantity, 50 oz., pale, acid, 1006, albumen 0. Total urea, 7.65 gm.; total solids, 13.98 gm.

*Cystoscopy.* — Bladder wall markedly trabeculated, intravesical bilateral enlargement with deep commissures above and below.

*Operation*, March 10, 1908, suprapubic prostatectomy. Prostate enucleated with difficulty, small and fibrous. Tube and urethral drainage.

*Pathological report.* — Fibrous hypertrophy.

*Convalescence.* — Patient took nourishment poorly after operation. Irrational and gradually failed and died March 19, ninth day. No bleeding. Temperature and pulse did not rise. Forty ounces or more of urine excreted daily, low specific gravity.

*Autopsy* showed hydronephrosis and chronic interstitial nephritis, arteriosclerosis, obsolete tuberculosis of apex of lung.

CASE 9. W. T., No. 157342. W. S. Age, forty-two years. Married. Glass packer. Entered hospital March 6, 1908. Service of Dr. Mixter.

*History.* — Gonorrhea eighteen years previously. Six weeks ago noticed urine was bloody. No pain or difficulty in urination. This was followed by frequency of urination. He was then catheterized twice daily by his physician. One previous attack of hematuria in November.

*Examination.* — Well developed and nourished young man. Anemic. By rectum, prostate markedly enlarged and hard, projects considerably into the rectum; the top of it can barely be reached with the finger. Residual not recorded.

*Urine* turbid, alkaline, albumen trace.

*Cystoscopy* showed a large pedunculated tumor partly smooth and partly villous, intimately connected with the prostate, thought to be malignant.

*Operation*, March 13, 1908, transperitoneal cystotomy, prostatectomy. Pedunculated tumor found springing from within the prostatic urethra. Tumor excised at pedicle and prostate shelled out entire. Peritoneal cavity which had been protected with gauze pads closed. Bladder closed with suprapubic drainage and tube. One gauze wick packed into prostatic bed on account of bleeding.

*Pathological report.* — Papillary cystadenoma of prostate.

*Convalescence.* — Uneventful except for epididymitis. Discharged April 16, thirty-fourth day. Wound healed, passing urine without difficulty.

*Subsequent history.* — One year later reported for examination. Feels perfectly well, urine clear. No urinary symptoms. Rises occasionally once at night. Residual not measured, some atrophy of right testicle since operation. Sexual power retained.

CASE 11. M. F. L., No. 159165. E. S. Age, sixty-four years. Married. Entered hospital July 6, 1908. Service of Dr. Brooks.

*History.* — About two years ago began to have trouble in passing water, difficulty in starting. Smarting and frequency. Rises four or five times at night. Feet and ankles have been swollen.

*Examination.* — Old man, rather feeble in appearance and behavior. Bladder distended nearly to umbilicus. Arteriosclerosis, edema of feet. By rectum, prostate size of an orange, tender. English web catheter passed with difficulty and tied in. Patient had chill and temperature of 104 that night. Leucocyte count, 30,000.

*Cystoscopy*, July 10. Bladder wall trabeculated, prostate not markedly enlarged intravesically.

*Urine* varied in twenty-four-hour amount from 35–65 oz. Urea, 14.5 to 24.75 gm. Alkaline, specific gravity 1012.

*Operation*, July 16, suprapubic prostatectomy. Prostate smaller than expected. Enucleated with difficulty, some hemorrhage. Tube drainage and seepage for twenty-four hours.

*Pathological report.* — Diffuse hypertrophy.

July 17, seepage very bloody. July 18, patient uremic, hiccoughing. July 19, patient became delirious and failed rapidly and died third day, probably of combination of uremia and hemorrhage in spite of energetic stimulation and infusion.

CASE 37. S. R., No. 170519. E. S. Age, sixty-three years. Married. Farmer. Entered hospital June 24, 1910. Service of Dr. Brooks.

*History.* — March, 1910, had a perineal operation done on another service. Lateral lobes were shelled out, median bar left. Patient had lived a catheter life for five years. Was unrelieved by the operation, having to use catheter entirely since discharge.

*Examination.* — Well developed and nourished. Somewhat obese, some edema of legs. Slight amount of prostatic tissue can be felt by rectum. Unable to pass any urine.

*Urine* cloudy, alkaline, 1010, albumen 0, sugar 0.

*Cystoscopy*, April 5, after first operation shows projecting lateral and median masses of prostatic tissue.

*Operation*, July 8, 1910, suprapubic prostatectomy. Third lobe size of bantam's egg and small portions of lateral shelled out.

*Pathological report.* — Glandular hypertrophy.

*Convalescence* uneventful. Suprapubic wound became tight in ten days. Poor control over bladder. With bladder filled with boracic solution can walk to bath room from ward and void. Wears bottle attached. Bladder training. Discharged July 26, eighteenth day.

*Subsequent history.* — Letter Jan. 9, 1911: "Sorry to state that I have not much control of the bladder, for I am leaking and have been since I felt the hospital. I am obliged to wear a urinal night and day." Jan. 24, 1911: Examination at hospital. General condition excellent. Wounds healed. Wears urinal day and night. Can pass about one pint at night voluntarily. No residual. Given directions and instructions for self training of bladder. No erections since last operation.

*(To be continued.)*

## Clinical Department.

### A CASE OF PEMPHIGUS CHRONICUS VULGARIS OF THE ORAL CAVITY AND LARYNX.*

BY ROCKWELL A. COFFIN, M.D., BOSTON.

HERETOFORE the above disease has been classed by the profession as one referable to the dermatologist rather than the laryngologist. A careful analysis of this case will show how important it is for the laryngologist to familiarize himself with the disease as it appears in the mouth, pharynx and larynx.

The uncommon occurrence of pemphigus and epidermolysis bullosa hereditaria, which are very similar in many respects, makes it difficult for one to study its various manifestations in order to be able to make a positive diagnosis except by differentiation.

* Read at a meeting of the New England Otological and Laryngological Society, Feb. 3, 1911.

Lewis H. Miller reported, in 1897, a case of pemphigus where the symptoms started in the oral cavity and continued for twenty months before finally making its appearance on the skin.

Dr. J. W. Farlow and others have reported cases extending over various lengths of time. The case here reported involved, very extensively, the oral cavity, epiglottis and larynx for over four years before finally making its appearance on the skin. Mosler reports a case lasting several years in the mouth alone, and Fuchs describes a similar case of eleven years' duration.

This case was shown at the first meeting of the New England Otological and Laryngological Society. At that time the case was seen by most of the members present and various diagnoses were suggested. Syphilis seemed to be the prevailing diagnosis, for, as there were no blebs present, it certainly was suggestive. The author had the good fortune to see two unmistakable cases some years before, and consequently, with the aid of elimination, a probable diagnosis of pemphigus was made.

#### PEMPHIGUS CHRONICUS VULGARIS.

Mrs. E. R. W., aged fifty-seven years, of dark and rather sallow complexion and small stature. Up to the time of her present trouble has enjoyed generally good health. No history of syphilis, scarlet fever, measles, diphtheria or malaria. No glandular enlargement of any kind could be found. Nursed mother while mother had typhoid fever. Twenty-one boils followed. No numbness of any part of the body. Abscess of hip when four years old. At times some dizziness, but otherwise no suggestion of any disturbance of digestion. Has had no eruption on any part of the body or face. Six months before the present trouble started, the teeth of the upper jaw were extracted. At this period she was under the care of a general practitioner for herpes and mercurial stomatitis, but without benefit. The blebs were first seen under the tongue and on the mucosa lining the cheeks. They were usually irregular in shape, and varied from the size of a pea to that of a quarter of a dollar, and after lasting a few hours would rupture, leaving a reddish surface covered with the slightly thickened epithelium which, in turn, would slough off, leaving a reddened surface underneath. Up to this time she had lost 30 lb. She then moved to Medfield, Mass., where she was under the care of a general practitioner, Dr. A. Mitchell, who referred her to the writer.

Jan. 1, 1905: Under surface of tongue raw, with here and there white, thickened and detachable bits of irregular shaped mucous membrane, with a similar condition on the mucosa lining the cheeks.

Jan. 2, 1905: Examined larynx and found bleb on tip of epiglottis. Was given Fowler's solution. Patient went away, and was next seen on

Nov. 8, 1905: The condition was about the same. While taking arsenic and iron she noticed a slight diminution in the size and number of blebs. Argyrol was applied and Dobell's solution was given as a mouth wash, but did apparently little good.

April 6, 1906: Remains about the same and complains of a disagreeable feeling in throat. Examination of larynx showed a single bleb on the left arytenoid cartilage.

The patient now moved to Noank, Conn., where she was under the care of Dr. Wm. Hill, who made applications to the mouth and throat, but with little

benefit. The writer did not see her again, but an interview with her daughter revealed the fact that she had blebs on her eyes about three years before she died (Feb. 1, 1910), and films formed over her eyes until she became totally blind. About one year before she died, blebs appeared over the entire body, and one on the foot became septic, which was the immediate cause of her death. About two years elapsed before the eyes were involved, and over four before the skin was affected.

The diagnosis was made by eliminating the following diseases:

(1) Syphilis. No history. Blebs not characteristic of syphilis. No loss of tissue or scars characteristic of syphilis.

(2) Lupus. This disease is not one with bleb manifestations, nor do the lesions appear suddenly and then heal spontaneously in a comparatively short time. Scars peculiar to this disease were absent in this case. No nodules of granulation tissue.

(3) Diphtheria. Absence of Klebs-Lœffler bacillus and duration of the disease.

(4) Leukoplakia. Consists of thickening of the epithelium which is usually very adherent, and the lesions are not ushered in with bleb formation. It has no reddened tissue under the epithelium unless there has been some acute irritation of the part. It is not transitory.

(5) Mercurial stomatitis. No history of having taken mercury in any form. No salivation or breath that is so often found in these cases. No tenderness of teeth when mouth is suddenly closed.

(6) Herpes. Usually found in small clusters, confining itself to one side of the soft palate, uvula or pillars of the fauces. Small and round and scarcely ever assumes the size and irregular shape that is so common in pemphigus. Often associated with herpes is acute pain, while pemphigus simply is uncomfortable. Herpes lasts usually only a short time and then disappears, only to appear later.

(7) Epidermolysis bullosa hereditaria. This is the the most difficult of all to eliminate, and, indeed, if we had not the history and skin lesions to help us, I doubt if it would be possible to distinguish one from the other except from location. In the one case which the author has seen of epidermolysis, the skin lesions appeared only at points of contact or trauma, and in like manner the lesions in the mouth follow the same rule. The lesions in pemphigus seem to appear on any part of the mucous membrane without reference to trauma.

## ACUTE TOXEMIA CAUSED BY INFECTION OF THE THROAT BY THE COLON BACILLUS.*

BY CALVIN B. FAUNCE, JR., M.D., BOSTON.

*(From the Pathological Laboratory of the Massachusetts Charitable Eye and Ear Infirmary.)*

THIS case is of unusual interest because of the rarity of colon infection in general, and especially because of the very unusual site in which the lesion here occurred.

Mrs. P., who had been in her usual good health, developed suddenly headache, chilly sensations, lumbar and joint pains. She did not complain of the throat. Twelve hours after the attack began, she suffered marked prostration, severe headache and high fever (temperature, 103). The throat was red and edematous throughout, both tonsils were much enlarged and a grayish-white exudate presented at the crypts. Her condition became steadily worse, so that in twenty-four hours after the onset of the disease the prostration was profound. The exudate on the tonsils had coalesced so that they both were completely covered. This exudate could be easily stripped off without bleeding. There was, in addition, a general herpetic ulcerative condition of the mouth. Cultures taken at this time were pronounced negative in regard to the presence of Klebs-Lœffler's bacillus, but the clinical condition was considered so suggestive of diphtheria that 6,000 units of antitoxin were administered.

Twelve hours after receiving the antitoxin the general condition had improved, the condition of the throat remained the same. Cultures taken at this time again failed to show the presence of the Klebs-Lœffler bacillus. The patient's general condition from this time on gradually improved; the throat cleared slowly and in about two weeks had practically assumed its normal appearance.

*Bacteriology.* — Examinations of all the cultures taken from the throat were negative to the presence of the Klebs-Lœffler bacillus. The first culture examined was not only negative to this bacillus, but contained in pure culture a very rapidly growing, short, almost coccus-like, Gram-negative, bacillus.

The organism produced a grayish, viscid looking, slightly elevated layer on both blood serum and potato. The water of condensation showed a gray turbidity. Bouillon cultures became clouded and there was sediment formation. The organism had a slight independent motion; it did not liquefy gelatine. It produced gas in glucose-agar stab. It coagulated litmus milk and turned it pink. There was marked indol production in Dunham's peptone solution. The above characteristics served to identify the organism as a colon bacillus.

Subcutaneous inoculation of the organism with its toxin (contained in the water of condensation) caused the death of a healthy guinea pig in about fourteen hours. It is, of course, well known that the colon bacillus may cause early death by toxemia in this manner.

As was to be expected, I found the toxicity of the organism was lost after several months' cultivation in the laboratory, and thus large amounts of the organism then inoculated into a guinea pig had no effect.

Ordinarily the colon bacillus has no clinical significance and exhibits no pathogenic action. It is commonly associated, however, with other bacteria in inflammation of exposed surfaces. In this particular case, therefore, it seems probable that the organism was a secondary invader and that there must have been a primary injury to the tissue, possibly produced by the streptococcus.

The fact that the culture was pure instead of containing the great variety of organisms usually found in cultures taken from the throat was no doubt due to the great reproductive power of this organism, which enabled it to overgrow all other bacteria present. Whether or not it likewise had overcome other organisms in the throat itself is uncertain.

The picture produced in this patient by the infection was that of an acute toxemia, as shown by the high temperature, marked prostration, severe headache, chilly sensations and lumbar pains. Evidently this organism was either especially virulent or the resistance of the patient lowered, so that the tissues fell easy prey to the bacterium. How the colon bacillus came to be in the throat is a matter of conjecture. Possibly regurgitation of the stomach contents lodged the bacillus on the previously inflamed membrane. It seems more probable, however, that the infection occurred as in typhoid fever from food, water or the hands.

* Read at a meeting of the New England Otological and Laryngological Society, Feb. 3, 1911.

The apparent improvement, after the administration of antitoxin, was probably coincidental with the successful manufacture of antibodies in sufficient numbers to protect.

The most striking feature of this case, aside from the unusual situation of the lesion, is that the offending organism, usually non-pathogenic, was in this instance strongly pathogenic.

## Medical Progress.

### PROGRESS IN THE THEORY AND PRACTICE OF MEDICINE. NEW METHODS OF DEMONSTRATING TUBERCLE BACILLI.

BY FRANCIS W. PALFREY, M.D., BOSTON.

THE finding of tubercle bacilli is an event of such importance in the diagnosis of any case that it is natural that attention should be constantly directed toward the improvement of technical methods of attaining this result. Satisfactory as has been the Ziehl method and its modifications when it has given positive results, the frequence with which positive results have been obtained only after many examinations, and the great number of negative results in cases which are later known to be cases of tuberculosis, leave much to be desired. Thus studies of new procedures aiming to accomplish the demonstration of tubercle bacilli where the older method has failed deserve general attention.

#### CONCENTRATION METHODS.

For many years attempts have been made to devise means by which tubercle bacilli in sputum and other excretions may be concentrated in small compass so that when present in numbers too small to be detected readily in the simple smear they may still be detected by examination of a medium in which by special procedures they have been gathered together. These methods depend upon dissolution of the solid organic material in which the tubercle bacilli lie, followed by sedimentation. Biedert,[1] in 1886, first employed this principle by boiling the material with sodium hydrate. Muhlhäuser,[2] and Czaplewski,[3] in 1891, modified and improved this technic, and Camen [4] in 1892 added the device since then extensively employed in laboratories of adding alcohol to reduce the specific gravity of the fluid to accelerate sedimentation. Other processes have been described by other authors.[5] But these earlier methods, on account of the necessity of boiling or of much manipulation of each individual specimen, proved more laborious than was justified by their only indifferent results.

In 1908, however, two methods were published which, while similar in principle to those previously discarded, have had claimed for them great superiority in results, and more or less simplification of technic. These methods, and another observation with regard to the staining of the tubercle bacillus, to be described later, have led in the past three years to a great amount of investigation and discussion.

Chief of these is the "antiformin" method of Uhlenhuth.[6] "Antiformin" is the name of a proprietary fluid for use as a disinfectant, a solution of sodium carbonate and chlorinated lime,* which Uhlenhuth found to have a remarkable power to reduce sputum and tissue to a homogeneous fluid state, with destruction of all bacteria except the tubercle bacillus. This action is obtained at room temperature, although more rapidly at higher temperatures. Cells and mucus are destroyed, leaving the bacilli free in suspension, from which they may be obtained by sedimentation, with or without centrifugalization, or by certain other devices which other authors have described.

The second method of concentration is that of Ellermann and Erlandsen,[5] called by them the "double method," which, while less convenient in application than the antiformin method, has given results far in advance of older procedures, comparing favorably with those of the antiformin method.

Many articles have been published describing these newer procedures, especially the antiformin method, giving numerous modifications of technic and estimates of their value. Large numerical statistics are given in but few instances, yet enough are reported to show that the methods deserve serious consideration. Practically no unfavorable opinions have been expressed, although evidence enough has not yet been collected to justify a final estimate of their true worth.

This being the case, it is desirable to review briefly the findings of those who have most carefully studied the question. A list of authors who have written on the use of antiformin is given below.[6–32] Many variations of technic are described, varying chiefly in the concentration of the antiformin solution used and in the manner of collecting the freed bacilli. The sputum or other material is treated with antiformin in varying amounts, making the concentration of the mixture all the way from 2% to nearly 50% antiformin. The mixture is shaken and allowed to stand until it is homogeneous, from thirty minutes or less to twenty-four hours, according to the strength of the solvent and to the temperature, some keeping it at room temperature, other at body temperature, others at 60° C. and others boiling. In concentrating the freed bacilli the chief reliance is upon long centrifugalization, but a few depend upon simple sedimentation by standing, others by reduction of specific gravity by adding alcohol or acetone, while others still make use of the principle of Lang and Nitsche [36] that tubercle bacilli tend to adhere to globules of the fluid hydrocarbons, benzol, ligroin, petroleum, ether or chloroform, which are emulsified in the antiformin-sputum mixture and allowed to separate, the bacilli being finally found at the zone of contact. When strong antiformin solutions are used, there is difficulty in fixing the smears. On this account some writers have washed the sediment with several changes of

* The method of preparation is given by Paterson [33] as follows: Sodium carbonate, 600; chlorinated lime, 400; Aqua dist., 4,000. Dissolve the sodium carbonate in 1,000 cem. of the distilled water. Triturate thoroughly the chlorinated lime in the remainder of the water. Filter. Mix the two and filter again.

water or salt solution in spite of the risk of losing some bacilli. Others have spread their sediment upon smears of untreated sputum from the same specimen.

Uhlenhuth's [7] own procedure is to treat the sputum with 20%–25% antiformin of equal volume, stirring and letting it stand for half an hour till homogeneous, then centrifugalizing thirty minutes, pouring off the supernatant fluid, washing twice by centrifugalizing with normal salt solution, smearing and staining the washed sediment by the ordinary methods.

Bernhardt [8] combines the antiformin method with the ligroin method of Lang and Nitsche [36] as follows: To 5 ccm. of sputum are added 20 ccm. of 20% antiformin, the whole is shaken and let stand with occasional shaking till homogeneous (about half an hour); 25 ccm. of water are added, then ligroin in a layer 3 to 5 mm. deep on the surface; this is shaken violently to a thick emulsion and allowed to stand till separated (twenty or thirty minutes). Material from the layer just beneath the ligroin is collected, dried on a warm slide, fixed and stained. Centrifugalization to hasten the separation of the ligroin defeats the object.

Goerres [12] adds to sputum water and antiformin to secure a strength of 25% antiformin in the mixture, shakes and lets stand four to six hours, then agitates gently to dislodge flocculi adherent to the walls of the tube and lets stand again till clear. He then pours off the supernatant fluid, adds water and centrifugalizes in special tubes stoppered at the bottom. He fixes smears from the sediment by spreading on fresh smears from the same specimen of untreated sputum. He has tried the ligroin technic of Bernhardt but has not found it so reliable as simple sedimentation.

Haserodt,[14] on account of difficulty in fixing smears, uses antiformin diluted to 5%, adding four or five volumes of this to the sputum and letting it stand twenty-four hours at room temperature, after which he treats it with ligroin in the same manner as Bernhardt.

Hüne [15] adds one or two volumes of alcohol to the sputum-antiformin mixture to aid sedimentation, centrifugalizing and refilling repeatedly. To the washed sediment he then adds two or three drops of glacial acetic acid, three or four volumes of distilled water and ether, shakes and finally centrifugalizes.

Huzuella [16] obtains bacilli by adding salt to his homogenized sputum to increase the specific gravity, and takes smears from the surface after the fluid has stood for a number of hours on a water-bath of 60° C.

Koslow [18] adds to sputum an equal volume of pure antiformin and shakes for five minutes. He then dilutes with 10 ccm. of water for each 1 ccm. of antiformin, and the same amount of a mixture of equal parts of acetone and ether. All is then shaken and let stand until three layers have separated. The middle layer which contains the bacilli and undissolved residues is dried, fixed and stained on a slide.

Loeffler's [20] technic is similar but makes use of chloroform instead of the acetone and ether. The chloroform is thrown down from the emulsion by centrifugalizing, and smears are taken from the layer just above it.

Merkel [21] praises the use of antiformin to detect tubercle bacilli in specimens of tissue. These he prepares by cutting in thin sections by the freezing microtome, after which antiformin acts as on sputum.

Rau [24] found the ligroin technic less successful than the simple antiformin method.

Schulte's [27] technic, chosen as the best by Trunk [31] after trial of many others, is as follows: To 10 ccm. sputum add 20 ccm. 50% antiformin; shake and let stand with occasional shaking for ten to thirty minutes till homogeneous; add 30 ccm. alcohol, shake and centrifugalize one-half to one hour; invert centrifuge tube, smear and stain.

A number of authors have used other reagents than antiformin for homogenizing, notably Bogason,[33] Hüne,[34] Hammerl,[35] Lang and Nitsche [36] and Zahn.[37]

The Ellermann-Erlandsen [5] method has been tested by Bierotte [9] and by Kögel. Kögel [38] gives the technic briefly as follows: To 10–15 ccm. of sputum add half as much 0.6% $Na_2CO_3$ and let stand twenty-four hours at 37° C. Pour off the upper portion of the supernatant fluid, centrifugalize the remainder and again pour off the fluid. To the sediment add four volumes of 0.25% NaOH, stir, boil and centrifugalize, smear and stain. Bierotte [9] confirms the efficiency of the method but notes as objections the disagreeable odor developed and the greater amount of time and trouble required in its execution as compared with the antiformin method, which gave in his hands practically equal concentration.

The results of these methods given by different authors are as follows:

Finkelstein,[11] in fifty-two sputa which had previously been positive, but at the time of examination showed no tubercle bacilli in the simple smear, demonstrated bacilli by the antiformin method in twenty-two. Lagrèze,[19] in fifty sputa negative in smear, found tubercle by antiformin in ten. Meyer,[22] among ninety-nine sputa, found fourteen positive by antiformin, although negative in smear. Paterson,[23] found five positive after antiformin among 23 negative in smear; Rau,[24] five positive out of eighteen. Reicher,[25] in one hundred cases, found that 27.5% of the positive results were obtained by the antiformin method, while the simple smear proved negative. Schulte,[27] in ninety-seven sputa, found seven positive only by antiformin. Weihrauch,[32] found twenty-six positive by antiformin, of which but eight were positive in simple smear. Brown and Smith,[10] by cultures from fifty sputa treated with antiformin, obtained growth from thirty-three of the thirty-five which were positive in smear and from four of the fifteen which were negative in smear. Goodman [13] found the antiformin process to give distinct increase in the number per field, but no cases were positive after antiformin treatment in which bacilli were not

found by the ordinary method. Sachs-Muke [36] reports two cases negative after antiformin treatment which were positive after $H_2O_2$ treatment, suggesting that the bacilli had been destroyed by the antiformin. Kögel,[38] using the Ellermann-Erlandsen method, estimates that the concentration of bacilli is increased between fifteen and thirty times by the process. Of routine sputa 28 to 31% of those which he found positive were found so only after concentration.

A possible source of error which must be considered in all complex methods is the occurrence of acid-fast bacilli in water as described by Brem [39] and by Beitzke.[40] But in many of the reports mentioned in the preceding paragraph, the tubercle bacilli were proved by animal inoculation.

### TUBERCLE BACILLI NOT TAKING THE ORDINARY STAIN.

A matter of great interest and of possible, although still uncertain, practical value is the question of tubercle bacilli which cannot be demonstrated by the Ziehl stain. It has long been described that material containing the virus of tuberculosis, capable of producing tuberculosis when injected into animals, may fail to contain demonstrable tubercle bacilli.[41] In 1907 Michaelides [42] published studies of animal material certainly tuberculous in which bacilli were not found in Zeihl or in Gram stains, but were demonstrable by Löffler's modified Gram stain. At the same time Much [43] demonstrated in similar material, not containing acid-fast bacilli, but capable of causing tuberculosis is animals, certain granular bacilli and granules, either single or in rows, as if contained in an invisible bacillus, stained by a modified Gram method and seeming to be related to the Gram-staining granules in ordinary tubercle bacilli. Soon afterward Much reported three cases of human tuberculosis in which acid-fast bacilli were absent but in which these granular bacilli and granules were found. He expressed the opinion that the tubercle bacillus occurs in three forms, the acid-fast, the non-acid-fast and the granular form.

These findings have attracted wide attention.[44–58] In studying these forms most authors have followed the staining method known as "Much II," which is performed as follows: Steam twice or stain cold for twenty-four to forty-eight hours in fresh carbol-methyl-violet (saturated alcoholic methyl-violet 10 ccm. to 100 ccm. 2% carbolic acid); dry with filter paper; Lugol's solution five to ten minutes; 5% nitric acid one minute; 3% hydrochloric acid ten seconds; acetone and alcohol equal parts to decolorize; wash with water and counterstain with very dilute carbol fuchsin, vesuvin or saffranin. A number [53] have combined this method with Ziehl's by staining in the first step with a mixture of one-fourth Much's carbol-methyl-violet and three-fourths carbol fuchsine, proceeding otherwise according to Much's directions and counterstaining with saffranin or Bismarck brown or weak methylene blue. Eisenberg [45] has collected a number of staining methods of value.

All who have written on the subject confirm the occurrence of Much's granules in tuberculous material and there is little reason to doubt either that they represent a certain stage in the life of the tubercle bacillus or that they are capable of producing tuberculosis. It is disputed, however, whether they are granules in young developing bacilli or in old resisting forms. It has been both suggested and denied that they are spores, but no decision has been reached as yet.

The more practical question as to their diagnostic value is also in doubt. Their appearance under the microscope is fairly characteristic, but whether it is possible to make them the basis for positive diagnoses is still unestablished. They occur as blue-black granules either single or in rod-like chains or in slender bacilli. Those occurring in visible bacilli would seem the most reliable. Since they are smaller than cocci, those occurring in chains are believed by Trunk [53] also to justify a positive diagnosis. Less importance can be attached to the single granules; the significance of these if they are still present after treatment with antiformin is probably too undertain to deserve attention.

The occurrence of the non-acid-fast bacilli and of Much's granular form is apparently frequent. They are reported as almost invariably present where the acid-fast bacilli are present, and in a considerable proportion of cases where acid-fast bacilli are not found.

Beyer [44] reports that of fifty-two sputa from clinically tuberculous cases thirty-four were positive both by Ziehl and by Gram, fourteen negative to both and four negative to Ziehl but positive to Gram. Rosenblat,[50] in a study of eighty sputa, found granules in rod form, in all which were positive to Ziehl and in one at that time negative to Ziehl but later positive. Schulz [51] finds the granular form of bacilli in the absence of ordinary bacilli to be especially common in cases of long-standing tuberculosis. Telermann [52] reports eight cases negative to Ziehl but positive to Gram. Weihrauch,[55] in ninety-five sputa, found thirty-six positive by Much's Gram stain after antiformin against twenty-six after antiformin alone and against eight after simple Ziehl-stained smear. The evidence adduced that tuberculosis was present in the cases where the granular non-acid-fast organisms were found in the absence of acid-fast bacilli is in most instances apparently conclusive.

Thus the literature of the past three years offers for further consideration methods which may deserve wide application in the diagnosis of tuberculosis. It must not yet be assumed that much that has been written is not still liable to contradiction. It may even be that none of these methods in the test of time will prove of permanent value. Yet such a presumption has been established in their favor that they cannot be ignored.

develop later belong to the putrefactive group. He has adopted the term of "acute intestinal toxemia" for the acute diarrheas of infancy which occur most commonly in the summer. He fed ten series of four kittens each on milk, condensed milk or modified milk, which had been boiled or sterilized and then incubated for twenty-four hours either with or without the addition of one or more of the following organisms: Bacillus subtilis, bacillus mesentericus vulgatus, bacillus proteus vulgaris. The course was essentially the same in all. After a longer or shorter period of apparent health there was a sudden onset of weakness, followed by stupor, with death in twenty-four to forty-eight hours. Diarrhea was not a constant symptom. No micro-organisms were found in the tissues. The pathological lesions were few and indefinite. The contents of the large intestine were always strongly alkaline. He concludes, therefore, that the disease is a toxemia and that the toxins are due to the action of putrefactive organisms on the intestinal contents, not to toxic substances formed before the food is ingested. The putrefactive organisms develop because the inhibitory lactic acid forming organisms have been destroyed.

He believes that the conclusions drawn from animal experimentation may be applied to the acute diarrheas of infancy, that is, the cause of acute intestinal toxemia in infants is the heating of the milk which destroys the lactic acid organisms. He believes, therefore, that infants should be fed on raw milk. He thinks that the danger of tubercular infection is insignificant. Clean, pure, raw milk is better than dirty raw milk, but dirty raw milk is better than sterilized clean milk.

## Book Reviews.

*Nurses' Handbook of Drugs and Solutions.* By Julia C. Stimson, R.N., Vassar A.B. Boston: Whitcomb & Barrows. 1910.

This compendium of materia medica should prove not only a valuable textbook for nurses, but a useful and convenient manual of information for other students.

*On Acute Intestinal Toxemia in Infants. An Experimental Investigation of the Etiology and Pathology of Epidemic or Summer Diarrhea.* By Ralph Vincent, M.D., Member of the Royal College of Physicians; Senior Physician and Director of the Research Laboratory, the Infants' Hospital, London. An address delivered before the Glasgow Obstetrical and Gynecological Society on Nov. 23, 1910. Pp. 83. London: Baillière, Tindall & Cox. 1911.

Vincent first calls attention to the well-known fact that the boiling of milk destroys bacteria, but not spores. The lactic acid organisms do not form spores; hence the organisms which

*The Prevention of Sexual Diseases.* By Victor G. Vecki, M.D. With Introduction by William J. Robinson, M.D. New York: The Critic and Guide Company. 1910.

This book is an exposition of the author's views on questions which it is becoming the fashion to discuss frankly. Its literary style is not idiomatic; its temper is one of rather characteristic Teutonic expediency. It recommends the licensing and supervision of prostitution. In the chapter on individual prophylaxis it advises chastity and continence; then, assuming that no one will follow the advice, on the principle of Kipling's

> "Be warned by my lot,
> Which I know you will not,"

proceeds to give instructions in the use of condoms and other supposed agents of protection. This is the advice which it suggests that a doctor should give to those who seek: Be good, if you can; I know you won't, so I will tell you how to be discreet. Whether this be good advice is a question that remains to be decided on its own merits. For the present its solution must rest with the professional conscience of the individual physician.

## HOMERIC PHYSICIANS.

THE antiquity of our medical craft is so great that there is not a literature whose earliest monuments do not contain mention of physicians and of their ministrations. To suffering humanity the healing art has always seemed endowed with such miraculous beneficence that from the remotest times it was considered to be of directly divine origin. Particularly was this so among the Greeks. Asklepios himself was the son of Apollo, who, as the god of light, of poetry and of medicine, represented, in the symbolism of Hellenic mythology, a pagan trinity, typifying the three noblest gifts of heaven to man. To the Greeks, rather than to their successors, the Romans, modern civilization is really indebted for its ideals in medicine; and medical tradition to-day, like so many other aspects of our life, is continuous with that of Greece, whose heroes still remain archetypes of excellence for our profession.

It is, therefore, particularly interesting for us to read in Homer descriptions of these demigods of medicine, which, though far from being contemporaneous with their lives, are yet essentially first-hand accounts from an age not so far removed in spirit as in years from that in which they lived. Perhaps the most striking thing in these accounts is that they represent the characters in question not as gods, but as men. To Homer Asklepios is not a divinity but a hero, "skilled in surgery and in the use of herbs," and his sons appear as fighters, chieftains and men of action. It was to later ages that these soldier-physicians owed their apotheosis, in a manner precisely analogous with that in which Arthur and Merlin and other semi-historic early British characters were later idealized in our national epic of fairyland and romance. Both instances are apt examples of the innate hero-worshiping instinct of mankind.

The first mention of Asklepios in Homer is in the "Catalogue of the Ships," that superb epic of proper names, unhappily so often neglected in the classroom. Here, even, Asklepios does not appear *in propria persona*, but is merely referred to as the father of his sons, a fate that has befallen many a less famous personage. These sons, Podalirios and Machaon, themselves "good physicians," or, as Pope paraphrases it, "divine professors of the healing arts," led the Greek forces from Tricca, from "rock-bound Ithome," and from Oechalia, cities of Thessaly; "and there went with them thirty hollow ships." It was primarily as generals that these heroes came; their medical functions were incidental, secondary, valuable avocations.

Podalirios is mentioned only once again in the Iliad, but Machaon is twice a conspicuous character. In the fourth book, he appears as the healer of "godlike Menelaos." A truce had been arranged between the Greeks and the Trojans in order that the quarrel might be decided by a single combat between Menelaos and Paris and though the former was victorious, the gods, in conclave on Olympus, determine that the war shall continue. Accordingly, to bring about a breach of the truce, Pallas Athene persuades Pandaros secretly to aim an arrow at Menelaos, wounding him in the groin. Agamemnon forthwith vows vengence on the Trojans, consoles his injured brother, and bids Talthybios, "the divine herald," to summon straightway Machaon, "son of the blameless physician Asklepios." Talthybios finds him "standing surrounded by the strong ranks of spear-bearing men," and delivers the message, which "rouses the heart in Machaon's breast." Machaon comes, and on reaching the spot "where fair-hair'd Menelaos lay wounded," "straightway from the close-fitting girdle he drew the arrow, and as he drew it out the sharp prongs tore the wound anew. And he loosed the all-gleaming girdle, and from beneath it the doublet and belt, toilfully wrought of brass. Now when he saw the wound, where the keen arrow sank in, he sucked out the blood and skilfully sprinkled on soothing drugs, which formerly Cheiron, well disposed, had given to his father."

This Cheiron, the centaur, "famed for his skill in hunting, music, medicine and prophecy," is mentioned again in the eleventh book of the Iliad as a teacher of Achilles. It is instructive,

in the above passage, to note Machaon's method of procedure. Modern surgery, doubtless, would hardly approve his insalivation of the wound, but the antiseptics employed were probably beneficial. At any rate Menelaos recovered.

The second mention of Machaon is in the eleventh book of the Iliad. Here, during the third great battle between the Greeks and the Trojans, Machaon is himself wounded below the right shoulder by a three-prong'd arrow from the hand of Paris, "spouse of fair-hair'd Helen." Seeing him fall, Idomeneus bids Nestor straightway go to him and take him swiftly to the ships, "for a physician is a man worth many others." This remark of Idomeneus, be it said, is one of the frankest compliments to our profession in literature. Nestor conveys Machaon safely out of the fight, through the Greek tents and beach'd ships to the shore, "and they wiped away the sweat from their tunics as they stood there in the breeze by the sands of the sea." Then they entered a tent, and Machaon was ministered to by "fair-hair'd Hecamede, daughter of great-hearted Arsinoös." The treatment apparently consisted in the administration by mouth of a large goblet of Pramnian wine, qualified with goat's milk cheese and flour, a beverage which it is noted that Nestor also shared. No local treatment of Machaon's wound is described The arrow evidently did not lodge, and perhaps, after a habit still noticeable among surgeons, Machaon cared little to have his own procedures applied to himself. Nevertheless it is recorded that he lay ill in the tent for some time.

At the close of this book both he and his brother Podalirios are mentioned again. The latter is "in the plain, abiding the fierce war of the Trojans," and Machaon "lies himself in need of a blameless physician." In the absence of both, Patroklos has to play the surgeon for the wounded Eurypylos, which he does in approved fashion, "for with his knife he cut from the thigh the sharp and bitter missile, and washed away the black blood with warm water, and on the wound he put an astringent, pain-subduing root, powdering it with his hands, which took away from him all suffering; and the wound was dried and the blood stopped." It would be interesting to know what this powder was. At any rate, the treatment seems to have been satisfactory, though without initial anesthesia.

These episodes, though incomplete, go far to indicate what manner of man was the Homeric physician, for nothing can excel in vividness the descriptive glimpses by which Homer reveals the life he knew, and makes it, in many respects, even more real than our own. Perhaps the fundamental character of the "blameless physician" has not changed so much as some other things in thirty centuries. It is not less gratifying to learn the respect in which our profession was then held than it is to see that in Homer's time a physician was not solely a doctor but a leader and a man of action as well.

## THE NEW YORK NEUROLOGICAL INSTITUTE.

The Neurological Institute of New York has issued its first annual report. The institute was incorporated in April, 1909, to develop an organization, especially designed, with adequate facilities for the improvement of the welfare of persons suffering from nervous diseases. The hospital department was opened on Dec. 1, 1909, and on Jan. 12, 1910, a license to conduct a dispensary was granted by the State Board of Charities. The Institute has had an extremely active year, and the present facilities of the hospital, which is domiciled in a leased building on East 67th Street, are so inadequate that many private patients are being treated at hotels and at other hospitals. The executive committee has endeavored, in its first year, to demonstrate the need for such a hospital, and, besides, to build up an organization which could not only conduct this hospital successfully, but would be capable of operating a much larger hospital in the city in conjunction with a sanatorium in the country. With these ends in view, the committee has paid high salaries in order to secure capable heads of departments, and as a result of its efforts it believes that it now has the nucleus of an organization capable of operating creditably a much larger city hospital at very little additional expense. The work of the Institute, the report states, is being watched by other cities. Repeated inquiries have been made as to its progress, and it is believed that it is only a question of time when many of the largest cities throughout the country will follow its example. The lease of the present quarters expires with this year, but can probably be extended for an additional year, and it is hoped that by the expiration of that the Institute will be provided with a hospital building commensurate with its needs. The following extracts are from the report of the executive physician, Dr. Joseph Collins:

"Although the Neurological Institute is designed for the study and treatment of nervous

and mental diseases, we have made no attempt to handle frank cases of insanity. We have had a large number of patients with mental symptoms, but in the majority of them these were not sufficient to constitute insanity. We believe that many cases of insanity have been averted by the prompt recognition of the gravity of certain symptoms and by the vigorous treatment which was adopted to overcome them. The number of surgical operations performed during the year, and their character, is set forth in the accompanying table. The work has grown rapidly, and already we have been obliged to ask for increased facilities for doing this branch of the work. It is probable that there is no department of the healing art in which specialization is more justified than that of neurological surgery. It is not hazarding one's reputation as a prophet to say that a generation hence the general surgeon will operate for brain and spinal cord disease as often as he does for cataract, — that is, never, unless compelled to do so. No man can become a competent neurological surgeon who has not had a neurological training and who is not at home in the experimental laboratory. These the Institute is aiming to provide, and we may legitimately venture the hope that within a short time those who are so unfortunate as to require neurological surgery will not be obliged to go from the metropolitan city of this country to small sister cities that they may have the skill of an expert. The report of the director of the laboratory shows that two thousand six hundred and eighty-six examinations have been made of the various excretions and secretions of the body. The clinical and histological laboratory, which is adjacent to the chemical and pathological laboratory, and which has been developed only during the last few months, is now completely equipped and in full operation. Among other ways in which this hospital distinguishes itself from all others are its departments for applied therapeutics, and it is safe to say that no other institution is so well-equipped for the utilization of water, heat and superheated air, electricity, Zander exercises, massage, calisthenics, re-educational movements. Really much of the success of the hospital is dependent upon the fact that patients at once realize that here something tangible is being done for the relief of their ailments; something more than the mere administration of medicines and custodial care."

Having referred to the useful work of the occupation and recreation departments, Dr. Collins states that this hospital has demonstrated three things: (1) the necessity for a hospital for the study and treatment of nervous and mental diseases; (2) the inadequacy of the facilities afforded by the present building; (3) the urgent need of a country branch. After speaking of some of the other requirements of a proper city hospital to care for one hundred and fifty patients, he goes on to say:

"Finally, and most important, it should provide ample facilities for instruction to physicians, nurses, trainers, attendants and special workers of all kinds. We believe that the vital element of our work is educational. Those who are sick may profit from the Institute's existence now, but the great profit that shall come to all mankind throughout the country will come through the ministration and example of those who are taught here in special fields. Such teaching must be personal and individual. It can be imparted in no other way."

## THE METROPOLITAN WATER AND SEWERAGE BOARD.

IN civilized communities, the importance of water-supply and of sewerage is so great and so obvious that every one would agree that their supervision and administration should be in the most competent and responsible hands. For a number of years in the Boston Metropolitan District this duty has been lodged with the Metropolitan Water and Sewerage Board, which has so conscientiously and efficiently done its work that to-day our community has an abundant and reliable water-supply and a sewerage system commensurate with its position as one of the great centers of population and enlightenment in this country. At the time of the Paris Exposition in 1900, the report of our Metropolitan Water Board, describing the extensive works then in progress, now completed, was submitted to accompany the exhibits contributed to that exposition by the Commonwealth of Massachusetts as evidence of its advancement in the arts, crafts and sciences of civilization.

A perusal of this report not only recalls the extensiveness of these metropolitan works and their present importance and value to the public health, but emphasizes the variety of special knowledge, as well as the probity and good judgment essential in those who control and direct the functions of the board. These are qualities which the board as a whole has abundantly shown, to its own distinction and the advantage of the community. It would seem desirable that there should always be on the board, which consists of three, one member who is a lawyer; one who, as a hygienist, is familiar and, if possible, associated with the work of the Massachusetts State Board of Health; and one with special engineering or business training. These positions are salaried, and are, therefore, at all times liable to be coveted by political spoilsmen. It has been our great good fortune hitherto that they have been filled for the most part by men not only of

personal capacity, but above suspicion or imputation of motives other than those of public-spirited service. For the credit and welfare of the community, it is sincerely to be hoped that this may always continue to be true in the future.

## MEDICAL NOTES.

Election of Dr. Fields. — Report from Baltimore, Md., states that at the session on April 19, in that city, of the National Association of Shellfish Commissioners, Dr. George W. Fields, commissioner of fish and game of Massachusetts, was elected president of the organization for the ensuing year.

Defalcation in German Red Cross. — Report from Berlin states that there has recently been discovered a defalcation to an amount equivalent to $50,000 in the accounts of the Women's Red Cross for the German Colonies. It is unfortunate that even organizations of medical beneficence should not always be free from malfeasance of this sort.

Measles Epidemic Aboard a Steamer. — On April 13, there reached Honolulu the steamship *Oteric* from Madeira, with 1,552 Portuguese immigrants aboard. During the voyage, 75 children died on the ship from an epidemic supposed to be measles. The source of this epidemic and the exact nature of the disease in question are to be investigated by a special committee.

Recrudescence of Cholera in Honolulu. — Report from Honolulu on April 18 states that four cases of Asiatic cholera have recently occurred in that city. This outbreak is regarded as a recrudescence of the epidemic which, it will be remembered, prevailed there from Feb. 24 to March 25 of this year. Persons leaving Honolulu by steamer have been forbidden to carry with them from that port any food or bottled water.

Doctor Svante Arrhenius. — Svante Arrhenius, the Swedish chemist who is at present giving a course of lectures on cosmogony before the Lowell Institute in Boston, is a man of considerable scientific distinction. He was born near Upsala in 1859, was educated in that town, and received his doctorate of philosophy in 1884 at Stockholm. He also holds medical degrees from Upsala and Heidelberg. He has made important contributions to the theory of dissociation and conductivity of electrolytes, and to the chemistry of the blood. He received the Davy medal in 1902 and the Nobel prize in 1903. His medieval name and his interest in cosmogony give an unusual flavor to the personality of this modern scientist and physician.

Purification of Swimming Pools. — At a recent meeting of the Illinois Water Supply Association, Prof. Severance Burrage, of Purdue University, described a method which he employed for disinfecting the water of swimming pools by means of chlorinated soda in the form of bleaching-powder. A pound and a half of the powder sprinkled on the surface of the pool each night was found to keep the bacterial content of the water below the hygienic limit for a week, whereas tanks in constant use without such disinfection need to be emptied and cleaned twice weekly. In Belfast, Ireland, it is reported that a method has been devised for the purification of swimming tanks by a process of constant filtration and aëration, which keeps the water pure and fresh for a long period of time.

### BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, April 18, 1911, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 40, scarlatina 37, typhoid fever 4, measles 193, smallpox 0, tuberculosis 26.

The death-rate of the reported deaths for the week ending April 18, 1911, was 21.35.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, April 22, 1911, was 258, against 222 the corresponding week of last year, showing an increase of 36 deaths, and making the death-rate for the week, 19.53. Of this number 128 were males and 130 were females; 254 were white and 4 colored; 158 were born in the United States, 97 in foreign countries and 3 unknown; 59 were of American parentage, 170 of foreign parentage and 29 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 52 cases and 6 deaths; scarlatina, 30 cases and 5 deaths; typhoid fever, 3 cases and 1 death; measles, 185 cases and 1 death; tuberculosis, 59 cases and 26 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 34, whooping cough 1, heart disease 34, bronchitis 8. There were 14 deaths from violent causes. The number of children who died under one

year was 53; the number under five years, 75. The number of persons who died over sixty years of age was 76. The deaths in hospitals and public institutions were 102.

Lecture on Sex Hygiene. — On April 18, Dr. Richard C. Cabot, of Boston, delivered a lecture on "Sex Hygiene" before the Fathers' and Mothers' Club in this city. There was a general discussion following the lecture.

Mad Dog in Boston. — The Boston Board of Health has recently issued a warning against a rabid dog which on April 17 ran through certain streets of the city. The animal was a small black Scotch terrier.

A Centenarian. — Miss Eliza Bullock, of Bristol, R. I., died of cerebral hemorrhage on April 21, the day after celebrating the supposed one hundred and first anniversary of her birth. She had been in excellent health until a few days before her demise.

Penalty for Failure to Clean A Back Yard. — Upon complaint of the Boston Board of Health, a householder of this city was last week fined $20 before the municipal court for failure to comply with an order to clean out the back yard of a house which he owned. From this sentence he appealed and was held in $200 bail.

Manufacture of Paper Cups. — The Massachusetts State Board of Health last week transmitted to the House of Representatives a report of its investigations into the conditions under which paper drinking cups are manufactured in this commonwealth. These conditions it finds satisfactory and believes that the public health is in no way endangered through the use of such cups.

A Living Centenarian. — Moses Carr, of Sangerville, Piscataquis County, Me., celebrated, on April 22, the supposed one hundred and first anniversary of his birth. He is said to be in active good health and to take long daily walks in all weather. Born in 1810, he came to Sangerville as a young man in 1832, and has spent his life there as a farmer and woollen merchant.

Birth of a Twentieth Child. — Last week was reported the birth of a twentieth child to Mr. and Mrs. John White, of Wakefield, Mass. During the twenty-four years since their marriage, Mrs. White has had 17 pregnancies, 14 single and 3 of twins. Of the 20 children, 16 are now living. It is believed that this is the largest family in the state of Massachusetts.

Case of Monocular Color Blindness. — It is reported that a case of monocular color blindness has recently been discovered in a student at Mt. Holyoke (Mass.) College. This is an exceedingly rare condition, only five similar cases having previously been described in the literature.

Tuberculosis Day, 1911. — It is announced from Hartford, Conn., that next Sunday, April 30, is to be observed throughout that state as Tuberculosis Day. This is in accordance with the plans of the National Association for the Study and Prevention of Tuberculosis.

Meningitis in Greek Immigrants. — Report from Fitchburg, Mass., states that in that city three cases of meningitis, two of them fatal, have developed among recent Greek immigrants. Other cases among Greek immigrants are reported as having occurred in the western part of the state. Reference to the present epidemic of meningitis in Greece may be found in the issue of the Journal for April 13 (page 550).

Death after Eating Jelly Beans. — In the issues of the Journal for March 30 and April 13, we noted the seizure at Providence, R. I., of large amounts of jelly beans alleged to contain talcum. On April 23 there was reported from Warwick, R. I., the death of a small boy with symptoms of acute arsenic poisoning after eating some similar beans. Samples of the suspected confectionery have been seized for further analysis.

Social Service at the Massachusetts General Hospital. — The fifth annual report of the social service department of the Massachusetts General Hospital describes the work done during 1910. The report emphasizes the fact that this work is supported solely by voluntary private contributions. At least $12,000 are needed for the expenses of the current year. During the five years of its existence, this department has dealt with 6,844 patients.

Instructive District Nursing Association. — A meeting was held, April 26, in Jacob Sleeper Hall, to promote the interests of the Boston Instructive District Nursing Association. Addresses were made by President Charles W. Eliot; by Professor Sedgwick, of the Massachusetts Institute of Technology; by Dr. Alfred Worces-

ter, of the Waltham (Mass.) Training School, and by Dr. Henry B. Favill, professor of clinical medicine at Rush Medical School, president of the Tuberculosis Institute of Chicago, and chairman of the committee of the American Medical Association on health and public instruction. The work of the association was described in detail, and its needs for the future outlined.

Four Hospital Bequests. — Among numerous charitable and philanthropic legacies in the will of the late Harriet E. Goodnow, of Sterling, Mass., filed for probate at Worcester, Mass., on April 17, are bequests of five thousand dollars each to the Massachusetts General Hospital, the Massachusetts Homœopathic Hospital, St. Margaret's Hospital and the New England Hospital for Women and Children. It is provided that in each instance this money be used for the establishment of a free bed, to be known as the "Waite Memorial Bed."

The Tyler Street Day Nursery. — On April 22, the Tyler Street Day Nursery ceased to exist, being authorised by the Supreme Court to turn over its funds, amounting to about $20,000, to the Boston Dispensary. The nursery was first started as a parish enterprise in connection with St. Paul's Church. In 1892 it was incorporated for "the purpose of encouraging mothers to support themselves and their children by caring for the children while the mothers were absent from their homes at work." From that time the nursery has constantly done a valuable work in the community. The income from its funds is now no longer sufficient to continue this work, and it has, therefore, seemed best to merge the nursery with the Boston Dispensary. Local conditions seem no longer suitable for maintaining a day nursery in that part of the city, and the Dispensary will, therefore, use the Nursery buildings on Tyler Street as a hospital for the sick and convalescent children of working people.

A Prolific Progenitor. — John M. Doucette, who died at Wakefield, Mass., on April 23, at the reputed age of ninety-six, is said to be survived by 260 direct descendants, namely, 10 children, 94 grandchildren, 147 great-grand children, and 9 great-great-grandchildren. Mr. Doucette, who was born in Ireland, always enjoyed excellent health and continued to do active outdoor work until within six months of his death. The prolific average of his family apparently persisted unimpaired through the first generation, but already shows evidence of decline in the second. It is probably safe to assume that under the conditions and environment of modern American civilization, the fertility of the third and fourth generations will not continue at the same rate of arithmetic progression.

Worcester City Hospital. — The fortieth annual report of the trustees of the City Hospital of Worcester, Mass., presents the record of work of that institution for the year ending Nov. 30, 1910. During this year the number of patients treated in the house was 4,630; the total number of visits to the Out-Patient Department was 19,309, and to the accident room, 811. During the Worcester typhoid fever epidemic in August and September, 135 cases of this disease were admitted to the hospital, of whom 10 died. There was only one nurse who contracted the infection. Thirty nurses were graduated from the training school in 1910. The need is emphasized of improved living accommodations for nurses by adequate addition to the Memorial Nurses' Home.

### NEW YORK.

Therapeutic Virtue of High Rock Spring. — The state reservation at Saratoga is now nearly complete. The most recently acquired spring is the well-known High Rock, which possesses the greatest historic interest of any of the Saratoga springs, as it was to this that in 1763 the Indians brought Sir William Johnson to be cured of rheumatism.

Bloomingdale Hospital. — The Board of Governors of the New York Hospital has elected Dr. William L. Russell to be superintendent of this hospital to succeed Dr. Samuel B. Lyon, who will retire July 1, after twenty-five years' service. Dr. Russell is at present superintendent of the Long Island State Hospital, and for a number of years was medical inspector for the New York State Commission in Lunacy.

Experimental Confirmation of Evidence in the Patrick Case. — In continuation of its efforts to secure the release from prison of Albert T. Patrick, whom it believes to have been wrongfully convicted of the murder of William M. Rice, the Medico-Legal Society requested the New York State Embalmers' Association to repeat the experiment made some time ago by Prof. H. S. Eckels, of Philadelphia. This was done in Albany, on April 19, the body employed for the purpose being one which had been embalmed for

a year, and the association has reported that, like that of Professor Eckels, their experiment showed that the testimony offered by the defense at Patrick's trial was correct. The prosecution contended that the congested appearance of Rice's lungs was due to the administration of chloroform and that it was impossible for the embalming fluid to have entered the lungs, as maintained by medical witnesses for the defense.

Work of the Milk Committee. — Dr. Paul Taylor, who, under the auspices of the Bureau of Municipal Research, was instrumental in securing many reforms in sanitary conditions in Philadelphia, has come to the city to superintend the summer campaign of the New York Milk Committee. It is announced that the subcommittee of the latter, the Committee for the Reduction of Infant Mortality, which has undertaken to raise the sum of $300,000 for the establishment and maintenance of sixty milk stations, is about to open the first of these at the Vanderbilt Clinic.

Stammering in Public Schools. — In a recent address before the Conference on Public Speaking at the College of the City of New York, Dr. E. W. Scripture said it was a question whether stuttering children ought to be permitted to mingle in the classes of the public schools, on account of the facility with which the habit of stammering, through conscious or unconscious imitation, is contracted from close association with stutterers.

The Fahnestock Training School for Nurses. — The annual commencement of the Margaret Fahnestock Training School for Nurses, attached to the New York Post-Graduate Hospital, was held on April 18, when twenty-nine women, the largest class yet graduated, received diplomas. Announcement was nade that an addition to the nurses' home, also the gift of William Fahnestock in memory of his mother, Mrs. Margaret Fahnestock, will be ready for occupancy in June. This new building, eight stories in height and situated just east of the present one, will practically double the accommodations for nurses and, in addition to dormitories, will contain an isolation ward and reception, sitting and class rooms and be surmounted by a roof garden.

Gift to the Montefiore Hospital. — Mrs. Adolph Scheftel has given $10,000 to the Montefiore Home and Hospital for Chronic Invalids to endow a ward for the treatment of patients affected with tabes. The gift is made in memory of her husband, who was a sufferer from the disease for many years.

Church, College and Hospital. — The public-spiritedness displayed in the following passage from the eloquent sermon preached by Bishop Greer, of New York, at the consecration of the choir and two chapels of the Cathedral of Saint John the Divine renders it well worth recording. The hospital referred to is the great St. Luke's Hospital, just north of the cathedral grounds, and the university, Columbia University.

"Here, then, is the value—a value beyond price — of a present-day cathedral as a force to make for righteousness in our modern life; not personal merely, but public, philanthropic and patriotic; a force that will help the people of this age and the people of this city, the representative city of the whole modern world, with all tribes, kindreds, tongues and voices coming and crowding in it, to realize more fully, and more faithfully to perform, their duty to their fellow-men and their country, through reverence for God. And here upon this eminence, the metropolitan eminence, does this our cathedral stand, with the hospital nearby as the symbol of the philantrophy of the age, with the university near-by as the symbol of the patriotic citizenship of the age; each of them to be inspired for guidance and for safety, for highest and noblest use, by that which this cathedral shall forever symbolize, encourage and promote. 'Love the brotherhood; honour the king'; philanthropy and patriotism, ethics and civics, both of them proceeding from reverence for God; shooting out on either side, in their best and purest form, as lateral branches from it."

Sanitary Condition of Bakeries. — On April 18, Mr. Fosdick, commissioner of accounts, submitted to the mayor a report which showed very unsanitary and unsavory conditions in a large number of bakeries, and recommended the transference of the supervision of all bakeries to the city. At present, it appears, the Health Department has no jurisdiction over them, and the state labor law, under which they are conducted, is very inadequate in its provisions, while at the same time these have been inadequately enforced by a small body of inspectors. In order to remedy these conditions the following amendments to the sanitary code are suggested in

the report: (1) All bakeries to be licensed by the Board of Health. (2) No rooms less than 9 feet between the floor and ceiling, and no rooms the floors of which are at a depth greater than 4 feet 6 inches below the level of the street or sidewalk adjacent to the building, to be licensed as bakeries. (3) A sanitary standard, specifically set forth in the code, to be observed in all bakeries. (4) All bakeries to be carefully and regularly inspected by the inspectors of the Department of Health, for the purpose of securing conformity to the requirements of the sanitary code. (5) The Board of Health to have power to close and seal any bakery not conforming to its orders after forty-eight hours.

Proposed Hospitals in the Bronx. — The State Board of Charities has refused to give its approval of the incorporation of the Bronx Hospital, a new institution which Dr. A. Jacobi and a number of other physicians, all but two of whom are residents of the Borough of Manhattan, desired to establish in a congested district of the Bronx. At a hearing on the subject which the board held some weeks ago, several prominent Bronx physicians objected strongly to the project, and a local movement for a hospital there is now said to have been started.

The Price of a Quart of Blood. — In answer to an advertisement of Mount Moriah Hospital recently, offering $25 to a suitable person willing to yield a quart of blood for a transfusion operation, more than one hundred applicants presented themselves. Although the advertisement called for men only, there was one woman among them, and she claimed to be in such fine condition that her system would stand the drain as well as that of any male.

Efficacy of Campaign against Tuberculosis. — In answer to the question repeatedly asked the State Department of Health, "Do the results obtained from the anti-tuberculosis campaign warrant this expenditure of time, money, energy and ability?" the last *Monthly Bulletin* of the department states that as a result of about three and one-half years of work of the united forces of the Health Department and the State Charities Aid Association, the facts seem to show conclusively that the work is worth all that has been put into it, and is worthy of still more money and effort on the part of the two organizations and of every individual in the state. In the way of general summary it is mentioned that 54 counties have been reached by some exhibit, and that in these counties 330 cities and villages have been visited and a total attendance of 1,430,531 secured, resulting in provision for 16 county hospitals, preparation already made for 8 others, and 18 counties now considering the establishment of hospitals, 30 visiting nurses, 24 dispensaries either in operation or provided for. While it is acknowledged that figures may be made to prove almost anything, tables and statistics are presented which appear to warrant the inference that already the campaign has had some appreciable effect on the mortality from tuberculosis. The *Bulletin* then goes on to say: "The department is glad to be able to make this report and to show that its use of the special appropriations for tuberculosis work is producing material and gratifying results. . . . No question exists regarding results, but further results cannot be expected unless more appropriation is made for this purpose by our legislature. Other states have seen fit to appropriate as high as $2,000,000 for the control of this disease, and New York state should not be the last to provide funds available for the eradication of a preventable disease which yearly takes away 14,000 people and costs the state $64,000,000."

1. Deaver considers that the relation of sex to chronic pancreatitis as compared with cholelithiasis is reversed. In view of the predominance of biliary infections in the female, this fact is significant as showing that there must be some essential difference in the factors which produce infection in the ducts of these closely situated viscera. No definite relation to eating or to any particular articles of food is evident in this disease. Sailer, however, finds that glucose is particularly distressing to patients suffering from chronic pancreatitis. The occurrence of nausea and vomiting occurring in attacks over persistent intervals is an important symptom. Painless jaundice associated with rapid wasting and loss of strength often leads even the expert to believe the patient is suffering from cancer, and operation is withheld which might result in a cure. Operation of an exploratory nature is, therefore, always indicated. Physical examination seldom affords much positive information. The treatment is essentially surgical in every case, with drainage of the biliary passages, early, before complications create a mortality.

3. Weston and Kolmer conclude from their work with vaccines in otitis media that the best time for the commencement of vaccine treatment is from the eighth to the sixteenth day of the discharge. Continued high fever, nephritis, toxemia and various intercurrent affections are contra-indications to the use of vaccines. Under vaccine treatment three times as many patients are cured within thirty days and permitted to go home as under the usual treatment. In general, cases of otitis media offer a fruitful and encouraging field for the employment of vaccines. [E. H. R.]

8. *WARTHIN, A. S. *Congenital Syphilis of the Heart.*
9. *GOLDENBERG, H., AND KALISKI, D. J. *Personal Experiences with the Use of Salvarsan (Dioxydiamidoarsenobenzol, or "606") in the Treatment of Syphilis.*

1. Thayer reports a case of hepatic cirrhosis with hematemesis and anemia in which he repeatedly heard a loud venous hum in the epigastrium immediately below the xiphoid, persisting for five years under observation, but absent in the last examination shortly before death, when marked ascites was present. A search through literature showed a considerable number of similar observations.

2. Cheney's article is an excellent didactic discussion of the present teachings as to the diagnosis of duodenal ulcer, with illustrative case reports. Following Moynihan, Cheney lays stress chiefly on the clinical history.

3. Abt and Strouse report two cases of diabetes following trauma in children. Both of these cases, in spite of continuous glycosuria and the occasional presence of acetone and diacetic acid, continued robust, in apparently good health, in marked contrast to the usual severe course of diabetes in children. Careful experiments were made to determine if possible any differences in metabolism from that of ordinary diabetes, but no such differences were found. The use of fresh vegetables and of the Von Noorden gruel resulted in raising strikingly the tolerance for carbohydrates.

4. Connor discusses the irregularity of respiration known as Biot's breathing, which differs from Cheyne-Stokes breathing in the absence of gradually increasing and diminishing movements, presenting rather more or less periodic deep dyspneic respiration, with intervals of apnea. Connor reports seven cases showing this type of breathing with tracings. Six of these were cases of meningitis and the seventh may have been meningitis. Twenty-four other cases of meningitis failed to show Biot's breathing.

5. Musser's article is a summary of the more recent studies of the disorders of muscular action of the heart which have resulted from the application of physiological

analyses to clinical cases, notably by Wenckebach and by Mackenzie. The article contains no original additions to the subject but can be recommended as a fairly clear and complete statement of current teachings.

5. Hoskins has made a critical study of literature as to the interrelation of organs of internal secretion, and in this paper discusses the findings as to the thyroid. He concludes that most of the available evidence indicates that the thyroid stimulates the adrenals; that hypothyroidism causes hypertrophy in the pituitary; that there is a relation between the thyroids and the gonads which are probably stimulated to normal activity by the thyroid; and that the suggested relation between thyroid and thymus is supported only by meager and conflicting evidence.

7. Fuller calls attention to the subject of fractures of the acetabulum, a rare injury and one which is not sufficiently recognized. He reports two cases, one reduced with satisfactory end result, and the other first seen and diagnosed by Schiller eleven months after the injury involving permanent disability. The fracture is produced by force transmitted through the femur, particularly if the femur is in abduction, forcing the head of the femur through the acetabulum into the pelvis. Abnormal fragility of the acetabulum may play a part. The symptoms and signs may be so slight that neither fracture nor dislocation are believed to exist; certain recognition may be possible only by x-ray. But in some instances a deeply sunken trochanter, shortening with eversion, and palpation of the head of the femur in the pelvis in low abdominal or rectal examination, may at once justify a positive diagnosis. Reduction may be effected by lateral traction on a band around the upper end of the thigh.

8. Warthin describes an especial form of interstitial myocarditis due to the presence of the spirocheta pallida and resulting from congenital infection, observed by him in twelve cases. Characteristic macroscopic changes were, as a rule, absent, but on microscopic examination throughout the myocardium were seen light-staining patches of fibroblastic tissue containing peculiar degenerating cells of fibroblastic or epithelioid type, with infiltration of plasma cells, especially about the smaller arterioles and capillaries. The muscle fibers in the neighborhood showed a peculiar pale degeneration. Spirochetes were demonstrated in great numbers.

9. Goldberg and Kaliski report their experiences with salvarsan in the treatment of syphilis. They have found that the rapid disappearance of lesions of syphilis after a single injection of the drug has been striking. They do not believe, however, that the infection can be permanently eradicated with certainty in one *coup* with the present mode of application and dosage. Their present opinion is that, until it is shown that repeated doses of salvarsan can be given with safety, when the Wassermann reaction remains positive after the second injection of a full dose, mercurial treatment should be instituted even in the absence of manifest symptoms. [F. W. P.]

## British Medical Journal.

### March 25, 1911.

1. *Rankin, G. *A Post-Graduate Lecture in Indigestion.*
2. *Rowlands, R. P. *Remarks on Hourglass Contraction of the Stomach.*
3. Farquhar, G. G. *Acute Dilatation of the Stomach; Gastrotomy; Recovery.*
4. Maylard, A. E. *The Treatment of Appendiceal Abscess with Pure Carbolic Acid and Iodoform.*
5. Leggett, W. *A Case of Idiopathic Dilatation of the Colon.*

7. Stevens, A. *An Analysis of 326 Cases of Asiatic Cholera.*
8. Short, A. R. *The After-History of Thirty Cases of Movable Kidney Treated by Operation.*
9. Gordon, W. *The "Cardio-Splanchnic Phenomenon" of Abrams.*

1. Rankin, in a general lecture on indigestion, describes "sthenic" indigestion, which apparently corresponds to our hyperacidity and which he treats in much the same way; "asthenic" indigestion corresponding to our hypo-acidity, and "fermentative" indigestion.

2. Rowlands discusses in detail some cases of hour-glass stomach with operation and then briefly discusses the pathology, diagnosis and treatment.

6. Thompson and Ross describe their experiments in cold-chamber treatment. After briefly discussing the subject in general and the previous work done on it, they give the details of their experiments on animals infected with trypanosomes. They found that animals subjected to the cold treatment did not develop the disease so quickly and that they lived longer.

8. Short analyzes the after-history of thirty cases of movable kidney treated by operation. The operations performed were the (1) transcortical suturing, 13; (2) fixation by capsule only, 8; and (3) pure carbolic acid and an iodoform gauze sling, 8. In twenty cases complete or considerable relief was afforded; in four the kidney worked loose; in several of the failures the cause was mistaken diagnosis. [J. B. H.]

14. Wieting. *Complete Congenital Lack of Teeth.*

4. Wechselmann describes in detail and presents two descriptive pictures of a new apparatus he has for subcutaneous or intravenous injections. One of its great advantages is the rapidity with which injections can be made. Thus, in one and one-half to two minutes, the same amount of salt solution may be injected as usually takes fifteen to twenty minutes. The method of using it is very simple.

11. Jacobsohn, in an article well illustrated, describes his device for passive motion. The device is not complicated and can be used by the patient, as it is so arranged that if passive motion of the arms or hands is desired, the feet and legs can do the work, and vice versa. [C. F., Jr.]

2. Fraenkel takes up the subject of differential diagnosis of tumors and aneurysms in the thoracic cavity. The diagnosis between tumor and aneurysm is difficult at times, and the differentiation of the kind of tumor is frequently impossible. He reports four cases of pleural tumor and describes the pleural endothelioma and discusses the place it should hold in the classification of tumors.

4. The primary erythema due to the Röntgen ray Brauer thinks is independent of the kind of apparatus used or the quality of the rays. It is not due to the warmth of the rays, the ultraviolet rays or the fluorescent light or electrical reactions, but to the Röntgen rays themselves. It seems to be independent of the character of the individual's skin. The intensity of the erythema depends upon the strength and length of rays, as does also the incubation period. The early pigmentation after x-rays depends in part on the result of the erythema and in part on stimulation of the existing pigment qualities of the skin.

[C. F., JR.]

16. GOLDSCHMIDT, J. *The Cholera in Madeira.*

1. In the light of his great experience, Kehr discusses briefly the indications, positive and relative, for operation in cholecystitis. He says that latent stones need not necessarily be removed unless cancer has appeared in the family, that when a stone has entered the ducts operation should be resorted to before three months have passed in order to obviate the danger of complication, and that for empyema of gall bladder or chronic obstruction, operation should be urged because life is threatened and spontaneous cure is rare. The danger for the operation at the hands of the experienced is slight unless complications have arisen, but these add greatly to mortality and are avoidable by earlier intervention.

He attributes the symptoms to inflammation, infection and obstruction rather than to the stones directly, and he makes the diagnosis of cholecystitis, cholangitis, or adhesions rather than gallstones because in about ten per cent of cases these conditions occur without stones.

2. Ebstein says that when the width of cardiac dullness is increased it should be seen whether this may not be due to a high diaphragm. If so, associated cardiac insufficiency can be relieved if the cause of the high diaphragm can be cured. Chronic constipation is one of these causes. It may also cause albuminuria and cylindruria. Therefore, before a bad prognosis is given, chronic constipation should be corrected if present. [G. C. S.]

33. *v. FRISCH, O. *Some Observations on the Technic of Tendon Suture.*
34. *LEWIN, L. *The Toxic Character of Metallic Lead, and Especially of Lead Bullets in Animal Bodies.*

26. From a careful study of 18 selected typical cases of appendicitis from Körte's clinic at Berlin, Ruge reaches the conclusion that early operation alone avoids abscess formation and peritonitis and that it affords the only possibility of preventing extensive adhesions. He believes that it is just as safe as the interval operation, and that it has the advantage of greater promptness, often of easier technic.

27. Hadda reports 27 cases of experimental arteriovenous anastomosis in dogs. He describes the technic and discusses the relative merits of end-to-end, end-to-side, and side-to-side anastomosis.

28. Stern reports two cases of sarcoma of the os calcis, and collects an admirable bibliography on the subject.

29. Stieda reports two cases, the first of resection of the upper half of the humerus for cystic tumor with spontaneous fracture, the second of pseudarthrosis of the left leg following osteotomy for deformity after intra-uterine

fracture. The former was treated by autoplastic from the tibia, the latter by three heteroplastics from an exostosis, from the ulna of a traumatically amputated forearm, and from the tibia of an amputated leg. The results in both cases were anatomically and functionally excellent.

30. Kron reports a successful resection of the left lobe of the liver for gumma, and concludes that the liver can be operated on as well as other parenchymatous organs.

31. Galpern analyzes the statistics of 175 gastric operations for benign disease from Spassokukotzky's clinic at Smolensk. There was a total mortality of 4%. End results after from one to nine years were observed in 128 cases.

32. v. Haberer reports 19 cases of primary resection of the colon from v. Eiselsberg's clinic at Vienna. There were in the series three operative deaths. The author comments on these and discusses indications and technic.

33. Discussing the technic of tendon suture, v. Frisch emphasizes the importance of early mobilization of the sutured tendon which is made possible by his new and reliable form of stitch.

34. Lewin considers the effects of metallic lead in the body, and advocates the early removal of lodged lead projectiles as a prophylactic against absorption.

4. BRÉAUDAT AND DENIER. *Rice Bran in the Prophylaxis and Treatment of Beri Beri.*
5. TRUCHE, C., AND ALILAIRE, E. *Hereditary Immunity of the Horse against Ricin.*

1. In this number of the *Annales* a description of more of the work done on typhus fever last year at Tunis appears. They describe their work on deciding on the properties of the virus. They consider that it is an ultramicroscopic virus. It offers certain peculiar characteristics when filtered which seem to depend somewhat on the method by which the serum is obtained from the blood containing the virus. In certain cases they have had positive results with a filtered virus. They find that it is destroyed at about 50 to 55° C. In vitro serum apparently has no action upon the virus. They then take up a discussion of their or others experiments on the etiology and immunity of the disease. This is followed by the blood picture in monkeys during the experimental disease which shows at first an increased leucocyte count in the early incubation period, a return to normal at the end of the incubation period, with another rise at the beginning of the fever period. Then follows a short description of typhus fever in humans and infants.

Conclusions covering their whole year's work end the article. [C. F., JR.]

This "quarterly digest of advances, discoveries and improvements in the medical and surgical sciences," edited by Drs. Hobart A. Hare and Leighton F. Appleman, of Philadelphia, presents a compendious, readable summary of current literature on the subjects in question, mostly from the second half of 1910. Much of the material has been reviewed in this department of the JOURNAL. The volume, in which also a few good illustrations are reproduced, is a useful "abstract and brief chronicle" of recent progress in medicine.

## Miscellany.

### IN MEMORY OF HENRY P. BOWDITCH, M.D.

THE following memorial note on the life and services of Prof. Henry P. Bowditch has been prepared for the American Physiological Society by a committee of its members.

At the death of Henry Pickering Bowditch there passed away a man who had notable influence on the development of medical and biological science in America. He was born in Boston, April 4, 1840, and was graduated from Harvard College in 1861. As a graduate he began the study of chemistry in the Lawrence Scientific School, but left, in November, 1861, to become second lieutenant in the First Massachusetts Cavalry, then starting for the front. After loyal and chivalrous service to his country during the remaining three and a half years of the Civil War, he resumed his studies in Harvard University and received, in 1868, the degree of Doctor of Medicine. Thereupon he went to France and Germany to learn from the masters of his chosen science, physiology, the aims and methods of research. Filled with the spirit of Bernard and Ludwig, he returned to the Harvard Medical School in 1871 and established the first American physiological laboratory for the use of students, a laboratory which soon proved hospitable to investigators in every phase of experimental medicine. For thirty-five years he was an energetic and inspiring teacher, and a leader in investigation. His studies of the peculiar functions of cardiac muscle, the indefatigability of nerves, the knee-jerk and conditions affecting it, the force of ciliary activity, and the growth of children, illustrate the range and originality of his researches. Apparatus invented by him and widely used in physiological laboratories attest his mechanical ingenuity. He was one of the founders of the American Physiological Society and was its second president. The traditions of the society, particularly its character as an association to encourage research, are largely the result of his initiative. His example and his genuine appreciation of new work as it was reported at meetings of the society were a wholesome stimulus to young men beginning physiological investigation.

To the larger interests of medicine he rendered important service by promoting reforms in medical education, notably by advocating and helping to introduce the four years' required course, and later by strongly urging greater freedom of election in medical study. The Harvard Medical School he served as dean for a decade of important growth, and the development of the school will long continue in directions which his wisdom foresaw. Among the most valuable of his activities was his repeated defense of animal experimentation against unreasonable legislative restrictions, an activity in which he secured victories likely to preserve freedom of medical research for many years to come.

The honors received by Dr. Bowditch were

many. He was a member of numerous learned societies in this country and abroad. He was a doctor of science at the University of Cambridge, and a doctor of laws at Edinburgh, Toronto, Pennsylvania and Harvard. In 1900 he was president of the Triennial Congress of American Physicians and Surgeons.

With sure and sober judgment Dr. Bowditch combined vigor and readiness of action which made him a natural leader. He was a never-failing source of stimulation and encouragement to all progressive movements aimed at professional and civic improvement, and his mind was fertile with ingenious and effective ways to secure the accomplishment of worthy ends. These qualities of leadership were combined with other qualities — keen interest, unfailing courtesy, fairness and good will — that won for him not only the friendship and life-long devotion of the foremost men of medical science in this country and abroad, but also the affection of his students and close associates. From the days of his youth, when he began the struggle for ideals, to his last years of failing strength, he met what life brought him with courage and cheerful humor; and he passed away as much loved for the beauty and strength of his character as he was admired for his achievements.

## ANCIENT REMEDIES FOR TOOTHACHE.

An item in the Dundee *Advertiser* quotes the following remedies supposed to have been employed by the ancient Romans for toothache:

"Take the head of a dog that has died of rabies, mix the ash with oil of Cyprus and inject the product into the ear of the affected side. A water snake's vertebra will serve to scarify the gum provided that it be obtained from a white skinned snake. Or for the same purpose may be used a lizard's frontal bone obtained when the moon is full, or, if that fail, a chicken bone will do, provided that it be dried in a hole in a wall and thrown away immediately after use. It is good treatment to inject into the ear oil of lemon, in which has been macerated either mallow bugs or sparrows' dung, even should this last give rise to itching. A worm fed on a particular herb or a cabbage caterpillar can conveniently be placed in a hollow tooth, but it is equally simple to chew an adder's heart. Prevention being better than cure, a sovereign preventive will be found in the eating of two rats a month."

It is probably true that a person with a severe toothache is usually ready to adopt almost any measure for its alleviation. The above prescriptions, however, are no doubt fair samples of much medieval necromantic therapeusis, and suggest the

"Eye of newt and toe of frog,
Wool of bat and tongue of dog,
Adder's fork and blind-worm's sting,
Lizard's leg and owlet's wing,"

of the witches' incantation in "Macbeth."

## THE USE OF CONDENSED MILK.

The Milk and Baby Hygiene Association of Boston has recently issued a report of its investigations into the use of condensed milk as a food for infants. The unfitness of condensed milk for this purpose is well recognized by the medical profession, but the popular statement of the fact in this bulletin may perhaps be of benefit. Moreover, the association finds that "if condensed milk be diluted with enough water to make a quart of Massachusetts standard milk, containing 3.35% of fat, the actual cost of the renovated fluid exceeds the price of ordinary milk, and in some cases that of certified milk." Economically, as well as hygienically, the use of condensed milk would seem to be undesirable except for occasional purposes of convenience.

## PARIS LETTER.

### Tincture of Iodine as a Surgical Antiseptic.

*[From Our Special Correspondent.]*

Paris, April 11, 1911.

*Mr. Editor:* One of the most surprised preparations in materia medica at the present moment must be our time-honored acquaintance, the tincture of iodine, and there is no gainsaying the fact that it has sufficient grounds for a meditation on the uncertainty of the things of this world. During all the earlier half of the last century this familiar reddish-brown liquid was one of the most important remedies in medical practice, so much so that in 1855 a certain Boinet published a large volume of eight hundred and thirty-five pages about it, entitled "*Traité d'Iodothérapie.*" Already at that time its remarkable antiseptic properties had been noted; fetid pus had been seen to lose its noxious qualities under its influence, and compound fractures had been found to heal without any of the terrible complications so frequent in those times when treated with tincture of iodine. In a word, it seems as though at that period the antiseptic era was on the point of being discovered, in connection with this preparation, some twenty years before the Pasteur-Lister day. The opportunity was there; all that lacked, apparently, was the man with sufficient perspicacity to descry the great discovery that was staring him in the face. That man, however, was not forthcoming. The reign of phenol, sublimate, formal and peroxide began, iodine tincture was practically relegated to the old woman's arsenal, and this marvelous preparation descended very nearly to the level of arnica and chamomile tea!

This period of oblivion lasted for nearly forty years, but now, by the agency of one of those disconcerting turns of the wheel of fortune, tincture of iodine has once more been raised to a position of real eminence in medicine, and suddenly, — within the brief space of a couple of years. In this short time it has not only regained the rank in the medical world that it ought never to have lost, but its penetration into the masses has been so deep that it has attained even to such remote regions as the cerebral substance of society women. One of them got her finger-end caught in the door of her carriage the other day and gave it a pretty lively squeeze, producing a small wound *par éclatement.* When I arrived I remarked in scornful tones, "What in the world did you put arnica on it for?" She was generous in her triumph, that I must allow; for of course she had a lovely chance to make some withering reply. All she said was, "Oh no! that isn't arnica; I drove to the nearest druggist and had the finger painted with iodine!" "The devil you did," thought I; "if these Red Cross lectures continue to rage throughout the land, the future of the medical profession will soon be even less roseate than it seems at present. For the idea is to me not inconceivable that within a delay

that is really more or less proximate, the physician is going to have to make his choice between some of the side-branches of his calling, — electricity, radium, x-rays, or mind-treatment, — or harakiri after the scorpion method. Certainly if I had a son who was going in for general medicine, the utmost degree of sympathy at my disposal would be extended toward him, as I think he will see the time when his profession will no longer be a living proposition.

Tincture of iodine, then, has been discovered to be the most marvelous antiseptic known, and, — details that enhance its virtues many times over, — one whose use is simplicity itself, that can be found anywhere and that can be safely put into almost any one's hands. From one point of view it has a similarity with salvarsan in that it is of particular use in very difficult cases, cases that proved almost beyond the resources formerly at our disposal. This will be referred to in a moment; for the present let me cite an instance or two that have come to my ears recently.

One of the younger surgeons here received an urgency call the other day to come at once to such and such a hospital for an amputation. When he arrived he found a man who had got his right hand badly crushed in handling wine barrels, with various fractured bones and wounds, the whole region being, of course, as dirty as possible. It had never occurred to the interne that any other treatment than amputation or disarticulation was to be considered; yet, with simple iodine paintings, this man made a perfect recovery with a quite serviceable hand.

Another surgeon friend of mine went one afternoon to see a lady patient on whom he had operated a short time previously for appendicitis. She told him that her last monthly period had missed entirely and that she was now feeling considerable pain in the pelvis. On examination he found a small mass back and to one side of the uterus, diagnosed extra-uterine pregnancy and told her she must have it removed without delay. That same evening at ten o'clock he was called to see her again; pain had increased and her condition and appearance had alarmed those about her. The fetal cyst had evidently ruptured during the evening, the patient presented all the signs of serious internal hemorrhage and my surgical friend found himself in presence of as serious an emergency case as any one need desire, as it is not easy in Paris to get anything done in a hurry. However, by dint of heating up the telephone wires he managed to get the patient transported to a clinic and his aids assembled by one o'clock. By that time his unfortunate patient's condition was highly critical, the bleeding was evidently continuing and there was no time to lose. It is easy to conceive that with the former methods of preparing an abdomen for laparotomy, the loss of time, combined with the rough handling necessary to throughly brush and scrub the skin, might have given this patient the finishing touch, whereas in this instance, while the surgeon was slipping on his sterilized India-rubber gloves, the assistant simply painted the abdominal surface gently with soft gauze dipped in tincture of iodine and held in a forceps, there was not the slightest delay or mauling of the patient, a rapid incision revealed an abdominal cavity filled with blood, the cyst was clamped at once, the usual means of treating severe loss of blood could then be brought to bear, and the surgeon was master of the situation. Such a case as this must, I think, be one of the surgeon's keenest satisfactions, a case in which he is authorized to feel that but for his intervention his patient would have succumbed without doubt in another hour or two. This same man operated an umbilical hernia in a dog for me the other day with the iodine process without even shaving the region; it seems that this is current practice in the experimental laboratories now.

The iodine tincture of the French pharmacies is a one in ten solution in alcohol. It should, whenever possible, be procured fresh; when old it is subject to two secondary processes whereby it becomes stronger and more likely to irritate: the development of hydriodic acid, and concentration through alcohol evaporation. The question is being studied whether it is really necessary to use this one-tenth solution; whether, for instance, this could not equally well be further extended with alcohol to at least one-twentieth, or whether aqueous solutions obtained with iodide will not be just as efficacious. For although it has proved to be one of the safest of all antiseptics, we all know that there are certain patients with a marked idiosyncrasy for iodine with whom small doses produce the most alarming symptoms, and in particular those of edema of the glottis. Thus in the case in point I personally have heard of one patient with whom a most distressing and persistent generalized eczema was brought on by a single application of tincture of iodine; and of another who actually succumbed from acute iodism under the same circumstances. Because, not only is the iodine being applied on normal surfaces, as in the above extra-uterine pregnancy case, or as has been done by different surgeons in emergencies when away from all facilities and they have painted their own hands in order to operate; and not only is it used on open and crushed wounds, and even on extensive denuded surfaces such as burns, but it is applied to severe solutions of continuity, such as a scythe wound, the surfaces being stitched together a few minutes later, and it is also injected into suppurating cavities or fistulas. Under these circumstances a certain amount of the iodine must remain behind; so that if an equal effect can be obtained by a less active solution, it is certainly to be desired that this point should be demonstrated as quickly as possible.

There is a trifling artifice that it is useful to know, in order to have it at one's disposal in instances when a modicum of mind-cure is necessary. Certain families keep tincture of iodine in stock and use it themselves on all occasions, just as others do their precious Pond's Extract or Antiphlogistine. One woman I know here gets Pond's Extract over from America by the demijohn, and has the most *absolute faith* in its virtues to cure nearly every affection her large household of family and servants presents. To prescribe to such a person a remedy that she is in the habit of using herself would simply be to lose caste in a very precipitous fashion; whereas if you sit down and gravely formulate

℞ Metalloidic iodine, 3
Spirits of chloroform, 30

the effect will be magical, as the druggist will sent her a beautiful cerulean blue solution which you caution her to apply with great care as it is very active, whereas it is in reality nothing but the familiar old one in ten tincture of iodine!

A point that I have been turning over in my mind is whether this preparation may not be excellent for medical use, and in particular for tonsillar affections. The peculiar efficacy of iodine tincture is said to be due to its marked power of penetration, which in turn depends on its alcoholic vehicle; to be really efficacious, then, it should be applied to a perfectly dry surface, all previous cleansing by washing, soaping, etc., impeding its action. Now in the throat a dry surface could scarcely be obtained; but by first carefully wiping off the tonsillar region something approaching such a condition could be produced; besides, the tonsil is not protected by any hard layer of epidermis. I have often used in the throat a preparation consisting in one part of tincture of iodine to two of glycerine, but have never been able to see that it accomplishes very much. This is perhaps due to a peculiarity that we find in phenol, which seems to lose many of its properties, causticity, toxicity, etc., when combined with glycerine. It will be interesting to see how the tonsil reacts to pure tincture of iodine without the glycerine.

I remarked above that the tincture of iodine is particularly effective in the very worst cases, and the type of these is the mechanic or train-hand, who gets one of his extremities mashed in the course of his work. Not only do these accidents present the very worst forms of lesions, — mangled and torn tissues, open articulations and compound fractures, — but the damaged region cannot be otherwise than in the filthiest possible condition. These cases, also, are generally somewhat long in getting to the nearest help, particularly in a railroad accident out on the line. It has really seemed to me worse than useless to attempt to clean up such an affair as a mechanic's hand mashed in a machine. Will not the cleaning send into the open wounds more germs than are there already? My surgical friend assures me that by filling up all the wounds with strips of sterile cotton soaked in some antiseptic fluid, and then operating with care, patience and benzine,

the thing can be accomplished; so I suppose we shall have to take his word for it. But however this may be, all doubts of the sort are removed with the iodine process. Here, the less you do the better. No cleaning at all; at the most remove fragments that are bound to go any how, and be chary about this, for I think that the longer we live the greater becomes our respect for what nature can do at a push, then paint everything, — skin wounds, fractures, — carefully with the tincture, not being afraid to go over a surface more than once, and pushing it into every nook and hole. Over that, *chiffonner* a lot of light gauze, then some cotton-wool, and a bandage, and the trick is done. Nothing simpler could possibly be desired, and a *trousse* of this sort, with brief directions, could easily be on every train and in every factory. Strange to say, the pain connected with the application is really insignificant; it can be spread over large burns with equal results. Fancy the revolution this process is going to effect in first-aid ambulances near the firing-line in war time!

What happens, then, after such a dressing as this? The tincture appears to give rise to a profuse serous discharge, which is taken up by the *chiffonnée* gauze, which must not be protected by any hermetic tissue. Usually such a first dressing can be left in place for twenty-four hours, though of course, if the discharge soaks through the gauze, this can always be removed, and as often as desired. The next day the dressing is changed and the tincture applied again. This daily change is continued so long as the discharge lasts, which is, as a rule, from four to five days. The surfaces then become dry and the dressing and painting need only be done every three or four days.

The cases of recovery that have been reported under this treatment sound really more like fairy tales than serious surgical work. What do you think, for instance, of a compound, comminuted fracture of the leg that had been carefully cleaned, reduced and sewed up by a surgeon, but when his effects failed lamentably and gangrene set in, this was opened by another man, thoroughly painted in every corner, *and recovered!* "S."

## SOCIETY NOTICES.

AMERICAN THERAPEUTIC SOCIETY. — The twelfth annual meeting of the American Therapeutic Society will be held in the auditorium of Building B of the Harvard Medical School, Boston, Mass., May 11, 12 and 13, 1911.

THE AMERICAN SOCIETY OF TROPICAL MEDICINE. — The eighth annual meeting will be held at the Tulane University of Louisiana, New Orleans, La., Thursday and Friday, May 18 and 19, 1911.

JOHN M. SWAN, M.D., *Secretary*,
Philadelphia.

THE BOSTON SOCIETY OF MEDICAL SCIENCES. — The next meeting will be held at the Harvard Medical School, in the amphitheater of Building D, on May 2, 1911, at 8.15 P.M. Papers will be presented as follows: Dr. Hans Aron, "Nutrition and Growth." Dr. Francis G. Benedict, "The Metabolism of Normal Women." Dr. A. W. Peters, "Some Aspects of the Problem of Estimating Sugar in Urine." Dr. Francis G. Benedict, "The Influence of the Ingestion of Food on Metabolism.

CLEAVELAND FLOYD, M.D.,
*Secretary.*

## RECENT DEATHS.

DR. CHARLES STEDMAN BULL, one of the most eminent ophthalmologists of New York, died suddenly from cardiac disease on April 17, at the age of sixty-six years. He was graduated from Columbia University in 1864 and the College of Physicians and Surgeons, New York, in 1868, after which he spent two years in the study of diseases of the eye in Europe. Dr. Bull was one of the chief surgeons of the New York Eye and Ear Infirmary, an institution on the staff of which he had been for nearly forty years, and he was consulting ophthalmic surgeon to the Presbyterian Hospital and St. Mary's Free Hospital for Children. From 1903 to 1907 he was president of the American Ophthalmological Society, and until recently was professor of clinical surgery, Department of Ophthalmology, in Cornell University Medical College.

DR. THOMAS F. SCULLY, a prominent practitioner of Rome, N. Y., and ex-president of the Oneida County Medical Society, died on April 19, at the age of fifty-one years. He was born in Greenbush, Rensselaer County, N. Y., and was graduated from the Albany Medical College in 1885. For several years he was health officer of Cohoes, and at the time of his death was surgeon to the City Hospital in Rome. At the last election in New York Dr. Scully was the Independence League candidate for Secretary of State.

DR. BARTLETT C. FROST, a retired physician of Phillipsburg, Warren County, N. J., died on April 16, at the age of eighty-one years. He had served as mayor of Phillipsburg for five terms.

DR. LEARTUS CONNOR, who died of cerebral hemorrhage on April 16, at Detroit, Mich., was born in Coldenham, Orange County, N. J., in 1843. He received the degree of M.D. from the New York College of Physicians and Surgeons in 1870. He was a member of the American Medical Association, and had practiced medicine in Detroit for many years. He was professor of physiology, clinical medicine and ophthalmology in the Detroit Medical College.

DR. ROLAND A. DAVIS, who died last week at Somerville, Mass., was born in Charlestown in 1846. He graduated from the Boston University Medical School in 1893, and had practiced medicine in Somerville since that time. He was a member of the Massachusetts Homœopathic Medical Society and of the Boston Homœopathic Medical Society.

DR. EDWIN FARNHAM, who died last week at Cambridge, Mass., was born in Philadelphia in 1843. He received the degree of A.B. from Harvard in 1866, and that of M.D. from the University of Pennsylvania in 1869. In 1874 he returned to Cambridge, and practiced medicine there until his retirement in 1908. During the last nineteen years of his active life he served as medical adviser to the Cambridge Board of Health. He was a Fellow of The Massachusetts Medical Society and a member of the Cambridge Medical Improvement Society. He is survived by one daughter and one son.

### SCHOOL INSPECTION IN SMALL TOWNS.

BY ARTHUR TRACY CABOT, A.M., M.D.

This paper, read before the American School Hygiene Association, is published here in the hope that it may encourage the trial of this plan of school inspection in other towns throughout the state.

This is a matter in which medical men should interest themselves and should bring to the attention of the school committees in their towns.

The thesis I shall advance and discuss in this paper is that the best school inspection and supervision in towns and small communities is obtainable by a nurse alone, and I shall support this position by citing the experience gained in a two years' trial of this sort of inspection.

In 1906 the Massachusetts Legislature enacted a law that "the school committee of every city and town in the commonwealth shall appoint one or more school physicians, shall assign one to each public school within its city or town, and shall provide them with all proper facilities for the performance of their duties as prescribed in this act: and shall assign one or more to perform the duty of examining children who apply for health certificates in accordance with this act; *provided, however*, that in cities wherein the board of health is already maintaining or shall thereafter maintain substantially such medical inspection as this act requires, the board of health shall appoint and assign the school physician." (Acts of 1906, 502.)

The methods by which this act should be carried out were further prescribed by statute, and finally it was ordered that "the expense which a city or town may incur by virtue of the authority herein vested in the school committee or board of health, as the case may be, shall not exceed the amount appropriated for that purpose in cities by the city council and in towns by a town meeting. The appropriation shall precede any expenditure or any indebtedness which may be incurred under this act."

The next year the last clause in regard to the appropriation of money was revoked, but this had little effect in increasing the effectiveness of the act, for a city or town not interested in this sort of work and not appropriating sufficient money is practically not called to account.

Fortunately, in the larger places there has been enough interest to lead to a pretty general adoption of school inspection, which has been carried out in a more or less thorough manner. In the small towns, however, but little real work has been done.

The failure to appropriate sufficient money for proper inspection practically then renders the act inoperative, and it is in this way that the school inspection has been totally neglected in many places, except so far as it can be carried out by teachers.

A thorough inspection by a competent physician is a rather expensive matter and is beyond the means of many smaller places Furthermore, it has been found very difficult to obtain thorough inspection by a physician, because in small places the physician's close supervision of the children is interfered with by the professional jealousy of the other physicians in the place.

When I say professional jealousy, I do not mean to condemn the feeling. The relation of a physician to the families under his care is a close one. It is one sanctioned by long usage and it is quite natural that a physician with the greatest public spirit should object to having children whom he regards as under his care inspected and thoroughly examined by a physician appointed by political influence. It is quite evident, too, that a school physician on good terms with his brother practitioners in the town would refrain from examining children in their families because it would be contrary to his instinct to meddle in such a way with another's patients.

The adoption of the plan prescribed by law has been prevented, then, first, by the expense of inspection by a physician, and, second, by the disapproval of the medical practitioners.

These difficulties are very real ones; they cannot be ignored or overridden; they must be recognized and avoided in order to bring about a general adoption of school inspection outside of the large cities.

I think that in Canton, Mass., we have found a solution for them, and a recital of our experience will perhaps be the best way of setting before you the solution to which I refer.

Immediately after the act above alluded to was passed, Canton appropriated $200 to provide for the school inspection and appointed a school physician. This sum was manifestly not enough to pay for a thorough inspection, and the school physician contented himself with occasional services to the school committee, and but a small part of the appropriation was spent. Accordingly in the following year only $50 was appropriated. You can imagine how little inspection was carried out under such appropriations.

Considering how this situation might be met, it occurred to us that by the appointment of a school nurse we might obtain, at a sum within the means of the town, the whole time of a trained person able to make all ordinary inspection.

We also saw that a school nurse directed to refer children who were found to be sick to their own family physician and who should afterwards merely follow them up and see that they went to their doctor would avoid the danger of exciting the enmity and opposition of the medical men in the town.

We further felt that the school nurse, being able to follow the children to their homes, could carry her teaching of proper hygiene into the families and in this way be a potent factor in improving conditions about the town.

The town of Canton has two school systems — one the public schools, managed and paid for by the town; and the other the parochial school, at which rather more than a third of the children in town are taught.

The head of this parochial school, Father John J. Farrell, was approached and at once approved of the plan, saying that he would be glad to favor it in every way he could, provided we would also inspect the parochial school. This was, of course, exactly what we wished, and it insured that all of the children of the town would be under trained supervision.

At the town meeting in 1908 this plan was presented to the voters of the town with a request for an appropriation of $500, which sum was appropriated without a dissenting voice.

A trained nurse interested in this sort of work was engaged, to begin her labors at the commencement of the next school year, and the manner in which she carried out the plan was so satisfactory that at the next town meeting the sum of $950 was appropriated to cover the work of the next school year.

This plan has now been in operation for two years, and it is the opinion of those who have watched the work that we have a thoroughly efficient system of inspection and supervision.

The nurse looks after nine hundred children, examines them at the beginning of the year and records the results in a card catalogue.

She afterwards keeps a record of any illness they may have and seeks in this way to have a complete medical history of all of the children in town.

Such children as show any infirmity of eyes, ears, throat or general condition are referred to their physicians and are afterwards followed up to see that they get advice and follow it. Such children as need attention of a specialist and are unable to pay for it are taken by her to a public clinic in Boston.

In addition to this care of the children's health, she has also given talks on matters of hygiene in the schools, and her visits to the homes give her opportunities to illustrate and enforce this teaching. Many of the children were found to have bad teeth. A public lecture was given in the town upon the proper care of the mouth, and the nurse followed this up by talks to the children in the schools.

Arrangements have been made with the dentists in the town that on certain afternoons of the week they give dental treatment to poor children needing it at half price.

In the first year we had almost no contagious disease to contend with. One case of diphtheria was found and quickly isolated. No further cases appeared. At the beginning of this school year there were five cases of diphtheria in town, which had appeared during vacation, all confined to one locality. After the opening of school seven more cases appeared, all coming from the same part of the town and pupils in the two schools which cared for that section. As each child fell sick the schoolroom in which it had been was fumigated and the children having adjoining desks were given prophylactic treatment with antitoxin. There has been no evidence that the disease has been given by one child to another in the school and there has been no spread of the disease to other sections of the town.

The co-operation of the board of health which achieved this control of what threatened to be an epidemic was most satisfactory and the school attendance served as a means of keeping a close watch of the children and worked to bring about a limitation of the disease rather than to spread it.

Carried out in practice, then, we have found the work of the school nurse thoroughly satisfactory in giving the town what seems adequate inspection and control of contagious disease. The nurse has also had time to follow up such cases of tuberculosis as were known to the Anti-Tuberculosis Committee of the Nursing Association. The nurse has found in the schools ten cases of children already tuberculous and eighteen cases of ill-nourished and anemic children who seem liable to be affected with tuberculosis. Plans are being discussed for providing an outdoor room for the use of such children.

I have given this somewhat detailed account of how this plan was accepted by the town of Canton in order to show the attitude of the townspeople toward school inspection. They showed themselves ready and eager to accept it the moment it was presented to them in a serviceable and inexpensive form. This result was largely due to their confidence in their school committee and their local board of health, both of which bodies favored the project.

Within the first year of this experiment I was consulted by the superintendent of schools in the neighboring town of Norwood and they soon after installed a school nurse. The town of Milton, on the other side of us, are now planning a similar arrangement.

It seems, then, that the people in the country districts are ready for this important step in prevention of disease, and it only needs a little encouragement on the part of influential people interested in public health to bring about the adoption of a method of school inspection which our experience shows to be effective and economical.

## THE DIFFICULTIES AND LIMITATIONS OF DIAGNOSIS IN ADVANCED CASES OF RENAL TUBERCULOSIS.*

BY HUGH CABOT, M.D., BOSTON, MASS.

To any one familiar with the progress made in the diagnosis and treatment of renal tuberculosis during the last ten years, the advancement of our knowledge must be eminently satisfactory. There is perhaps no department of genito-urinary surgery in which the application of new methods has been crowned with more success and consequent benefit to our patients. We have reached the position where it is generally possible to lay down the facts with regard to the conditions in the urinary tract before operation with an accuracy which is nearly absolute. It is, therefore, well that we should, so to speak, take account of

* Read at the meeting of the North Central Section of the American Urological Association, Chicago, Jan. 5, 1911.

stock and see in what directions our diagnosis is still faulty and to what extent our conclusions must, therefore, be based upon an insecure foundation.

By all odds the most important result of ten years of work has been the proof that renal tuberculosis is, in its earlier stages, almost invariably unilateral, and if we except the cases of the diffuse miliary type, the statement might be even more absolute. This knowledge has come as a result of the intelligent use of the cystoscope, ureter catheter, functional tests of the renal activity, bacteriological examination, guinea-pig inoculation and finally, demonstration of the facts at operation. So accurate has become our knowledge as a result of these investigations that we have come to insist upon a detailed knowledge of the condition of the sound kidney before advising operation. But even with all these methods intelligently applied, there are certain types of genito-urinary tuberculosis in which error is difficult to avoid. This is particularly true of two classes of cases.

First, cases occurring in the male with undoubted tuberculosis of the genital tract, primary in the epididymis or prostate with bladder involvement in which the determination of the conditions in the kidney is often difficult.

Second, cases occurring in the female in which the disease is primary in the Fallopian tubes, with bladder involvement, obscuring the renal condition. One might add the reported cases of primary bladder tuberculosis, though of these I have no experience. It may be held that the experienced observer employing all known methods of diagnosis will not fall into these traps, but it must, of course, be admitted that all observers are not of equal experience and that in some cases at least the pitfalls are well devised to ensnare the unwary. I will briefly note a few cases in which difficulties of this kind have resulted in error or delay of diagnosis.

Case I. An unusually vigorous, well-developed young man of twenty-two living in good hygienic conditions developed frequency of urination and pain on micturition without obvious cause. Accompanying this there was slight urethral discharge, which was for a time believed to be a gonococcus infection, though the gonococcus was never found. The surgeon under whose care he was at that time discovered the presence of an enlarged prostate and regarded the case as one of acute prostatitis. Under simple remedies the condition quieted down, though pus never entirely disappeared from the urine. A year later he had a sharp hematuria accompanied by exacerbation of symptoms. This ceased spontaneously and he was again comfortable. A year later, two years after the onset, another attack of hematuria. Careful examination at this time showed the prostate considerably enlarged and moderately tender; there was no involvement of the epididymis on either side. Cystoscopy showed considerable inflammation of the base of the bladder, not involving either ureter orifice. Ureter catheterization showed marked kidney damage on the left, a normal kidney on the right. Inoculation experiments showed tubercle bacilli from the bladder urine, from the left kidney and a few from the right kidney. Catheterization of the right ureter was again done, no tubercle bacilli found and repeated tests showed that kidney to be sound. Left nephrectomy was followed by recovery.

Case II. A man of twenty-five seen at the hospital with frequency of micturition which had existed for five years. The bladder was much contracted and the urine always contained pus in large quantities. By rectum the prostate showed no enlargement, but marked tenderness, the whole region was much infiltrated and the separate structures could not be made out. Inoculation experiments from the bladder urine showed tuberculosis. Under rest in bed and careful treatment the bladder capacity was increased to four ounces. Cystoscopy then showed a much ulcerated bladder in which the ureter orifices could be seen only with difficulty and the left only could be catheterized. The urine from this kidney showed tubercle bacilli by inoculation. Functional tests showed poor function of both kidneys and the process was therefore regarded as bilateral. A year later his condition had improved somewhat. His general health was good, he had gained weight and was better in all respects except in regard to frequency of micturition. Functional tests with indigo carmine showed practically normal function of the right kidney, very little work done by the left. Proceeding on the basis of the previous experiments it seemed probable that the left kidney, which was still the source of pain, was the most important factor in his discomfort and it was therefore removed. Upon section this kidney showed no tuberculosis, extensive hydronephrosis with comparatively little kidney substance remaining and a few small calculi in one of the sacs. The error in this case occured for two reasons. First, because the observations of the previous year were relied upon, and second, because the findings of one ureteral catheterization were too implicitly followed.

Case III. A girl of eighteen, after a severe illness thought to be typhoid, complained of pain in the region of the right kidney, accompanied by fever, tenderness and tumor. The attack quieted down without careful study, though it was discovered that there was pus in the urine. These attacks continued to occur at intervals during the next four years, at the end of which time she first came under observation. Her general condition was even then good. There was marked tenderness in the region of the right kidney and exquisite tenderness in the right lower quadrant of the abdomen, with considerable muscular spasm. Frequency of micturition was troublesome, but not excessive. The urine contained much pus. More extended examination was advised but neglected. Six months later her condition was much less satisfactory. She had lost weight and was having more or less continuous fever. The attacks of pain in the right side had continued. Cystoscopy showed considerable ulceration of the base of the bladder, most marked on the left, but without involvement of either ureteral orifice. Kidney function was good upon both sides and the urine from the kidneys was normal. Operation showed the case to be one of bilateral tubercular salpingitis. Patient did not survive.

Case IV. A woman of thirty-five, fifteen years ago had pulmonary tuberculosis for which she was sent to a sanatorium and has since lived an out-of-door life. Eight years ago had pain in the region of the left kidney. At that time cystoscopy and ureteral catheterization showed left renal tuberculosis and a sound right kidney. No bladder involvement. For reasons which do not appear, probably because of the lung process, no operation was advised. Since that time the improvement in her general condition has been marked and maintained; the lung process has

remained quiescent. Eight months ago cystoscopy and ureteral catheterization showed that the left kidney was still actively tuberculous but was secreting little urine. At this time tubercle bacilli were found in a catheter specimen from the right kidney, though the urine was in other respects normal. Bilateral tuberculosis was believed to exist and no operation advised. One month ago was first seen by me. Her condition is essentially the same as eight months ago, except that there is now marked and progressive bladder involvement. Cystoscopy is difficult. There is ulceration of the base of the bladder. Left ureteral orifice is stiff, dilated and retracted, only pus comes from that side. The right ureteral orifice is apparently normal, urine collected from that kidney apparently normal in all respects, though the results of guinea pig inoculations are still pending.

These cases show various of the difficult situations and some of the reasons for error. Case IV seems to me to show the danger of depending too much upon laboratory reports and too little upon the general appearances and probabilities. I am inclined to think that the tubercle bacilli found eight months ago were either a contamination, a faulty observation or a confusion with the smegma bacillus. That bladder contamination of the specimen collected by ureter catheter may occur is illustrated by Case I, if further proof of the assertion is demanded. I am firmly of the opinion that more stress should be laid upon the absence of inflammatory products in the urine collected from the kidney than on the discovery of a few tubercle bacilli. Where the urine is apparently normal, further evidence is required before condemning that kidney. The importance to be attached to the absence of findings of inflammation in the kidney has been ably pointed out by Chute.

### MANAGEMENT OF DIFFICULT CASES.

I now want especially to invite your attention to that class of cases in which our methods of study are handicapped and, therefore, unreliable, owing to the advanced stage of the disease and the contraction of the bladder. Our security in diagnosis depends almost completely upon the ability to catheterize both ureters. Where the bladder is contracted and irritable, holding from one and a half to three ounces, the investigation becomes difficult and at times hazardous. The ureter orifices can sometimes not be seen or, if seen, cannot be catheterized. The presence of tuberculosis can be proved by examination of the bladder urine.

The first problem to be solved is whether the case belongs to the so-called upper or lower type; in other words, whether the tuberculosis is primarily genital or urinary. Careful physical examination will sometimes throw much light upon this question, but in a certain number of cases both types exist simultaneously. I do not wish here to discuss cases belonging to the lower type, though they present numerous and interesting problems. Assuming for the sake of argument that the cases under discussion are primarily renal, what is our duty?

### THE OUTLOOK WITHOUT OPERATION.

There are few ills in the domain of medicine which have more variegated possibilities of suffering than genito-urinary tuberculosis. I need not describe to you the horrors of such an existence and I have no fear of contradiction in the assertion that unless surgery offers some relief, medicine will afford none.

### THE OUTLOOK WITH OPERATION.

If our attempts to relieve these patients by surgery are fortified at every turn by the greatest accuracy attainable under the circumstances it is scarcely possible to make them worse and I can hardly regard an operative death as a worse alternative to continued existence. Now assuming that the massive focus of infection is renal and that the involvement of the bladder, or in the male the prostate, is secondary, what has surgery to offer?

First, If one kidney is sound, the outlook may be said to be fair and considerable improvement extremely probable. We know that the lesions of the bladder and even of the prostate improve in some cases enormously, in others considerably, after the removal of the primary focus alone. We know that still further improvement of the bladder conditions may be brought about by the wise, cautious and systematic use of tuberculin. I believe that in many cases still further improvement may be obtained by the use of autogenous vaccines of the colon bacillus, which is a common successor of the tubercle bacillus in these cases.

Second, Operative and post-mortem records have shown that even in these severe and advanced cases there is large possibility that one kidney is thoroughly sound. In support of this I may cite the two following cases.

CASE I. A girl of twenty-two with a long history of bladder disturbance. When first seen she was much emaciated, with fairly constant pyrexia, great frequency of micturition and considerable pain in the region of the left kidney. Cystoscopy was extremely difficult. The left ureteral orifice was finally made out and catheterized, the urine showing much pus and many tubercle bacilli. The total kidney function was poor. It seemed eminently probable that both kidneys were involved, and no operation was advised. She lived for months in torture and died of a left-sided perinephritic abscess, with a normal and apparently competent right kidney. This case could, I believe, have been saved by operation.

CASE II. A girl of twenty with a history of increasing bladder disturbance for five years. When first seen she was in good general condition, with some pain in the region of the left kidney. The bladder was much contracted, never holding three ounces. Cystoscopy was extremely difficult. Neither ureter orifice could be seen. Indigo carmine was excreted in fair amount by the left side, apparently not at all by the right, though the observation could not be long prolonged. Under the belief that in her good general condition one kidney must be sound, the left side was explored. A large kidney apparently normal though with a much dilated ureter was found. On the strength of this the right kidney which was converted into a caseous suppurating mass was removed. At the present time, two years after operation, she is in an apparently

normal condition. The urine is free from tubercle bacilli and the bladder holds ten ounces. There is some frequency of micturition due to a polyuria which has the appearance of that due to interstitial nephritis.

These cases are of course only suggestive but the suggestion is strong.

### MORTALITY.

Much stress has been laid upon the question of mortality, and we have rightly prided ourselves upon having reduced the operative risk from one which was almost prohibitive to one which is almost negligible. The most recent cases will, I believe, show a mortality below 2%. Admirable as this reduced mortality is, our desire to achieve it must not blind us to the fact that it is not the final goal. He who allows his fear of mortality to prevent him from attempting cure in desperate cases is not fulfilling his whole duty. In these advanced cases where the outlook without operation is almost absolutely bad, mortality should be a minor consideration. Even if the death-rate should be one in three, the restoration of the other two cases to a life of comparative comfort would be a notable achievement well worth the risk. Therefore I believe that in this connection the discussion of mortality should have a minor place.

In dealing with these difficult cases our attitude should, I think, be different and we should apply standards different from those applicable in the earlier cases. If we cannot catheterize the ureters, cannot state with accuracy the comparative function of both kidneys, our boasted accuracy is gone, but we can still martial a considerable array of data to further our conclusions and furnishing at least presumptive evidence.

### DATA WHICH CAN BE OBTAINED.

First, The general condition of the patient. It is of much importance to know how a given patient has withstood the inroads of the disease. Where general condition has been well maintained, weight, strength and appetite are good, we may presume that the patient is still master of his condition. The general physical examination gives data of much importance. Absence of any demonstrable foci in the lung is evidence of good resistence. Evidence of healed lesions elsewhere, as in the bone, is of value. A careful examination of the kidney regions may enable us to guess which side is involved. Pain, though valuable, is misleading, as it may be due to the dilatation of the ureter on the sound side, which, I believe, frequently occurs in these contracted bladders. I will not pursue this topic further except to point out that the general estimate of the patient's condition is not without value.

Second, Data to be obtained from the urinary tract. Though our investigation in detail is much handicapped, we are by no means deprived of all evidence. It is important to study the twenty-four-hour amount of urine, the total solids and ability of the remaining kidney tissue whether on one or both sides to respond to the stimulation of artificial polyuria. These observations are particularly of value if it can later be demonstrated that one kidney is doing the bulk of the work and are presumptive evidence of the adequacy of that kidney.

Cystoscopy though much handicapped gives valuable evidence. In a proportion of cases, in my experience small, it can be satisfactorily carried out by ordinary methods under local anesthesia. In a larger proportion such an examination cannot be made, as the length of time required to gather facts is an unnecessary torture to the patient, and general anesthesia, or spinal anesthesia, should be resorted to. It has seemed to me that spinal anesthesia was particularly suited to this work and was less dangerous than general anesthesia. The danger in these cases from general anesthesia comes chiefly from the undesirable effect upon the kidneys, which are here always handicapped, dangerously so when we are dealing with bilateral disease. I am perhaps more impressed by this danger because several years ago I lost a patient from uremia following a simple anesthesia at which only a short cystoscopy was done. During the last year we have employed spinal anesthesia on several of these cases and it has worked to our satisfaction. Pain has been entirely obliterated, an ounce, sometimes more, has been added to bladder capacity for the time being, and anesthesia has lasted in satisfactory degree from an hour to an hour and a half. I believe it to be the anesthetic of election in the present state of our knowledge, for these conditions.

By means of the cystoscope we can get certain general information.

First, The general character of the bladder process with suggested localization on one side. We can study the work of the ureter orifices in some cases, though often only by the swirl of urine without seeing the orifice itself.

Second, The excretion of indigo carmine has seemed to me of considerable value in these cases, though I admit its limitations. It will often enable the observer to locate the position of the ureter among the bladder folds, thereby demonstrating retraction of the ureter orifice due to ureteritis and peri-ureteritis. The promptness of the excretion is of importance; the character of the jet will throw light upon the condition of the ureter, whether normal or dilated. When indigo carmine is excreted promptly and in good amount from one side, and little or not at all from the other, it is strong evidence of the soundness of the one kidney. It is as far as I know the only functional test applicable to these cases.

Third, In a considerable number of cases radiographs are of value by showing increased density of the affected kidney, and if caseation and phosphatic deposits have occurred, the complete outline of the kidney and ureter may be very clearly shown. This gives nothing more than contributory evidence, but is of value in making up the complete picture.

An examination thus conducted will enable us to group the cases into two classes.

First, Patients in good general condition secret-

ing a urine good in amount and total solids, in whom indigo carmine is excreted almost entirely from one side. The presumption in these cases is strong that one kidney is sound, the other extensively diseased and operation may be advised with a considerable chance of success.

Second, This group will contain the larger number of cases, the doubtful ones. Their general condition will be fairly good, the general kidney function fair. Indigo carmine may be excreted from both sides, neither showing much advantage over the other. These are the really hard cases and those in which error is most likely to occur.

For cases belonging to this second group I am inclined to advise exploratory operation. I am quite aware that this is adopting a method discarded and repugnant to modern methods of diagnosis. On the other hand, there is a point at which these methods fail us, and yet we are not justified in refusing to give a patient the benefit of any doubt that exists. If exploration is allowed to take the place in any degree of careful systematic study, then it is a reversion to discarded methods and not to be advised, but when other methods fail it may become the method of election. There are certain cases with marked involvement of the bladder in which by no other method at our disposal can it be asserted with absolute certainty that there is kidney involvement. On the other hand, if the bladder process is secondary to that in the kidney, and if one kidney is sound, the sick kidney should be dealt with. It is less dangerous to explore efficiently than to leave a patient with one bad and one good kidney. It is less dangerous to explore and get the facts than it is to guess at which kidney is involved and run the risk of removing the worse of two seriously damaged organs.

### METHOD OF EXPLORATION.

In planning an exploration, certain facts must be recognized at the outset. To cut down upon one side and trust to the examination of the other side with the hand passed across the peritoneal cavity is to run a grave risk of error. It is not safe to trust to the examination of the surface of the kidney even if well exposed to reveal the extent and character of the process, and it is nothing short of flying in the face of providence to trust to an exploration at arm's length and in a cramped position. Any exploration to be efficient must be bilateral and must involve a knowledge not only of the kidney and upper portion of the ureter as felt by palpation, but some knowledge of the urine excreted by that kidney. These propositions have been laid down by as good authorities as Israël, Caspar and Rovsing, though comparatively little has been written bearing upon this particular question. Most writers who mention it advise a bilateral lumbar incision. It has seemed to me that the anterior muscle-splitting incision was more satisfactory. It gives ready access to the kidney and the upper half of the ureter. It is quickly made and quickly closed, giving a strong and remarkably painless wound. Particular stress must be laid on always exploring both kidneys. Israël has pointed out the importance of opening the ureter on both sides and collecting the urine directly from both kidneys. To this Caspar has added the value of injecting indigo carmine and observing the secretion. The apparent condition of the kidney and the ureter is an unsafe guide. In a considerable number of the cases the ureter on the sound side is dilated, though it is rarely, I believe, thickened in a way to deceive those familiar with tubercular ureteritis and peri-ureteritis. A kidney completely converted into a caseous mass may feel surprisingly normal. With the catheters in both ureters, from which urine should be allowed to drain for ten or fifteen minutes, much knowledge may be gained. This coupled with information gained by examination and palpation should enable the expert to arrive at an opinion. Nephrotomy done for exploratory purposes seems to me objectionable. It will fail to show the exact condition of the kidney unless a very free incision is made. Large incisions carry notable risk of secondary hemorrhage and result in wound contamination which may be serious. That nephrotomy as a palliative operation for drainage may occasionally be justifiable I am prepared to admit. The examination of the kidneys being completed, the wounds may be closed if both kidneys are diseased or normal, or one wound may be closed and nephrectomy done upon the diseased side.

In light of recent experience with spinal anesthesia in cases of damaged kidneys, I am inclined to regard this as the anesthesia of election, at least for the exploratory part of the operation. Anesthesia extending well up to the costal margin is readily obtained and is entirely satisfactory for the exposure and opening of the ureters. The urine can then be collected and conclusions drawn without subjecting the patient to the strain of general anesthesia. Should nephrectomy be decided upon, it may either be done at once under a general anesthetic, or postponed to a future occasion. We have not found spinal anesthesia satisfactory for nephrectomy and do not advise its use, but for the preliminary determination of of the kidney function, I believe it will lower the mortality in properly selected cases.

Obviously these methods are not to be recommended to the inexpert or to the occasional operator, and he will probably do well to avoid what must always be an unprofitable field from a point of view of permanent cure. On the other hand, when done by those with experience and sound judgment, I feel sure it will save much discomfort and many lives at a cost not high considering the outlook without operation.

---

THE Milwaukee County Medical Society appointed a committee at a special meeting, April 16, "to investigate the attitude of the Christian Science church toward the practice of medicine with especial reference to the treatment of contagious diseases." It was reported that there were, on that day, fifty-three cases of scarlet fever in one ward of the city being treated by Eddyist healers.—*Jour. Am. Med. Asso.*

# AN ANALYSIS OF FORTY-SIX CASES OF PROSTATECTOMY.

BY LINCOLN DAVIS, M.D., BOSTON.

## Abstracts of Case.

### SUPRAPUBIC PROSTATECTOMY FOR BENIGN ENLARGEMENT.

(Concluded from No. 17, p. 612.)

Case 38. W. G. S., No. 171169. E. S. Age, seventy-five years. Married. Clerk. Entered hospital Aug. 2, 1910. Service of Dr. Brooks.

*History.* — Gonorrhea when a young man. Two years ago had retention of urine, relieved by one catheterization. Five months later, again, retention. Since then has had increasing difficulty and straining at micturition. Retention about every five weeks during past year requiring one or more catheterizations. Urine becoming increasingly foul. For last three weeks has required catheterization twice a day; for two weeks has been on constant drainage. Comes in with retained catheter.

*Examination.* — Spare, well-preserved old man, somewhat deaf. Pupils equal and react to light. Heart sounds irregular but strong. Pulse 100. Râles at bases of lungs. Abdomen negative. Right inguinal hernia. Urine very foul, contains much pus. Rectal examination: Generally enlarged, non-tender prostate of normal consistency. Constant drainage.

*Urine* very foul, acid, 1010, albumen large trace, sugar 0. Sediment, much blood and pus.

*Cystoscopy* not attempted on account of impossibility of clearing bladder.

*Operation*, Aug. 8, suprapubic cystotomy. Bladder cavity very small. In the median line, about one inch from internal urethral orifice, rounded opening of a diverticulum was seen which would admit forefinger. Cavity of diverticulum quite extensive, explored with sound, contained 3–4 oz. of thick offensive pus. Tube inserted into diverticulum. Bladder wall closed about tube. Patient drowsy and mildly uremic. Drainage for three weeks without material improvement.

*Operation*, Aug. 31, laparotomy, cystotomy, suprapubic prostatectomy. Peritoneal cavity opened by free incision from pubes to umbilicus, intestines walled off with gauze. Diverticulum explored, found to extend to the left of median line behind and around the ureter. Peritoneum dissected off posterior wall of bladder and left lateral wall of pelvis. Attempt to remove diverticulum or invaginate it abandoned on account of difficulty of freeing adhesions. Peritoneal cavity closed. Prostate, which projected moderately into cavity of bladder in form of a collar, enucleated. Considerable bleeding. Gauze packed into cavity from which prostate came. Drain placed outside of bladder to base of diverticulum. Rubber tube to bladder.

*Pathological report.* — Glandular hypertrophy.

*Convalescence.* — Sept. 3, wicks out of bladder. Good recovery, wound closed slowly. Oct. 2, passing some urine through urethra. Oct. 15, wound closed, passing urine naturally, urine much cleaner. No residual. Bladder washes quite clear. Discharged forty-fifth day after second operation.

*Subsequent history.* — Jan. 12, 1911, patient returned for examination. General condition excellent, considerable spasticity of legs, walks with cane. Passes urine naturally and without straining, perfect control. Holds water two hours or more during day, urinates three or four times at night. Urine pale, slightly turbid, with shreds, no odor. Soft rubber catheter passes easily, residual ¼ oz. nearly clear urine. Wound healed solidly. Diverticulum apparently drains itself.

Case 39. S. S., No. 171252. E. S. Age, sixty-three years. Married. Farmer. Entered the hospital Aug. 6, 1910. Service of Dr. Brooks.

*History.* — Gonorrhea twenty-five years ago. Eight years ago began to have difficult urination. Three years ago had retention, since then has used catheter once or twice a day. Passes urine every hour at night and about every two hours during day.

*Examination.* — Heart and lungs negative. Left inguinal hernia. By rectum prostate considerably enlarged, not tender. Patient catheterized himself, getting 11 oz. of residual urine.

*Urine* acid, 1008, albumen trace, sediment — pus and blood.

*Cystoscopy.* — A large, white, rounded mass to the right side of and above urethral orifice, either a stone or an encrusted prostatic lobe. Cystoscopy indicates advisability of suprapubic operation.

*Operation*, Aug. 13, suprapubic prostatectomy. Soft round stone lying free in bladder removed. Prostate projected markedly into bladder cavity. Enucleated. Very little bleeding.

*Pathological report.* — Glandular hypertrophy with inflammation.

*Convalescence.* — Slow but uneventful. Normal urination not established until Sept. 14. Good control. Discharged Sept. 17, thirty-fifth day. Passing urine naturally. Residual, ¾ oz. No. 29 sound passes easily.

*Subsequent history.* — Letter Jan. 23, 1911. Feeling fine, wound healed, urine clear. Passes urine once to three times at night. No leakage. Gets tired easily.

Case 41. S. G., No. 171502. S. S. Age, fifty-five years. Married. Peddler. Entered hospital Aug. 20, 1910. Service of Dr. Porter.

*History.* — Denies venereal. General health excellent. About three months ago, while attempting to urinate, was seized with severe pain and passed blood for two days. After this had incontinence at night, frequency and straining by day. On July 6 entered the hospital, the diagnosis of hypertrophied prostate was made and operation advised. Patient refused. Returned Aug. 20 with constant dribbling and considerable pain.

*Examination.* — Robust, healthy man. Chest negative. Bladder distended half way to umbilicus. By rectum prostate symmetrically enlarged. Residual, 10 oz.

*Urine* cloudy, acid, albumen 0, sediment — few leucocytes and blood corpuscles.

*Cystoscopy*, July 6. Bladder markedly trabeculated, moderate intravesical enlargement of lateral lobes with median bar, contour smooth, no evidence of malignancy. Aug. 24, condition about same.

*Operation*, Aug. 25, 1910, ether, suprapubic prostatectomy. Gland enucleated through a median incision in floor of bladder. Bladder wall remarkably thick and unyielding. Very little bleeding. Tube drainage.

*Pathological report.* — Glandular hypertrophy.

*Convalescence.* — Uneventful at first. Sept. 16, patient passing urine, suprapubic wound nearly closed. Sept. 19, suprapubic wound reopened and all urine came through it. It was impossible to pass catheter into bladder. Under ether suprapubic wound reopened and bladder explored. There was no sign of an outlet bladder, floor of bladder healed smoothly across. Sound passed by urethra is arrested very close to bladder cavity, pushed through by force, opening dilated, and large catheter tied in. Patient draining well. Oct. 6, patient discharged against medical advice on account of refractory conduct. Suprapubic wound still open. Subsequent history not known.

Case 46. H. L. M., No. 173998. E. S. Age,

seventy-seven years. Married. Retired. Entered hospital Jan. 16, 1911. Service of Dr. Harrington.

*History.* — No serious sickness. Eight years ago had retention of urine. Has used catheter ever since. Epididymitis once two years ago. For the last four weeks has been in bed most of the time on account of pain in the bladder and rectum when up and about.

*Examination.* — Emaciated, senile, moderate arteriosclerosis. Chest negative except for a few râles in back. Heart sounds normal, pulse intermittent. Rectal examination — prostate moderately enlarged, smooth and of normal consistence.

*Urine.* — Acid, 1024, albumen slight trace. Sediment — pus, round cells, rare cast. Twenty-four-hour amount, 28 oz.

*Cystoscopy.* — Moderate intravesical enlargement of lateral lobes. Large stone lying free on floor of bladder. X-ray shows shadow of stone of estimated diameter of 1¼ inches.

*Operation*, Jan. 19, 1911, spinal anesthesia. Suprapubic cystotomy. Removal of large stone. Small prostate enucleated in two portions, very little bleeding. Tube drainage and gauze pack.

*Pathological report.* — Glandular hypertrophy.

*Convalescence.* — Considerable shock. Pulse very feeble, energetic stimulation, salt infusion, etc. Considerable difficulty in swallowing for first few days. Sitting up on fourth day. Jan. 26, tube removed, considerable sloughing of wound. Jan. 28, catheter drainage, wound granulating. General condition excellent. Feb. 7, catheter removed, passing water for first time in eight years. Feb. 22, discharged, thirty-fourth day. Wound closed, urination natural, residual adout 3 oz.

*Subsequent history.* — April 1, 1911, general condition excellent, no urinary symptoms. Residual, 1 oz.

SUPRAPUBIC PROSTATECTOMY FOR MALIGNANT DISEASE.

CASE 2. J. S., No. 149840. W. S. Age, sixty-three years. Married. Contractor. Entered hospital Oct. 10, 1906. Service of Dr. Richardson.

*History.* — For two months, difficult and frequent micturition. Has had retention on a few occasions requiring catheterization. Urinates about every half hour by day and four times at night. Considerable pain.

*Examination.* — Well developed and nourished man in good condition. Prostate large, firm and hard.

*Cystoscopy* under ether. No signs of malignancy. Left lobe projects more than right.

*Operation*, Oct. 20, suprapubic prostatectomy. Prostate very adherent removed en masse with great difficulty; the specimen included the whole prostate and both seminal vesicles. Some bleeding. Tube drainage and gauze wick.

*Pathological report.* — Malignant adenoma involving vesicles.

*Convalescence* uneventful. Discharged Nov. 22, thirty-third day. All urine passed by urethra, wound nearly closed.

*Subsequent history.* — Died about four months later of cancer.

CASE 3. T. McG., No. 152899. W. S. Age, sixty years. Married. Entered hospital May 13, 1907. Service of Dr. Mixter.

*History.* — Gonorrhea thirty years ago. Operation at Massachusetts General Hospital sixteen years ago for stricture of urethra and piles. No symptoms since operation until present trouble. Two months ago began to have frequency and pain with difficulty in starting stream. Frequency ten times a day. For last two weeks complete retention, requiring catheterization. Has lost 15–20 lb. in weight during last three months.

*Examination.* — Poorly nourished. Arteriosclerosis. Coated tongue. By rectum prostate small and hard, not nodular. No. 24 sound passed easily to bladder, no stone.

*Urine* acid, 1020, albumen 0.

*Operation*, May 16, partial suprapubic prostatectomy. Prostate forms collar about internal urethral orifice. Portion of prostate shelled out with difficulty. Fibrous ridge behind meatus burned through with cautery. Suprapubic tube.

*Pathological report* missing. Verbal report — carcinoma.

*Convalescence* uneventful. June 6, patient voids without difficulty. June 11, residual 6 oz. Patient voided lying down, not considered a fair test.

*Subsequent history.* — June 23, 1908, returns for examination. General health fair except for weakness. Not able to work. Passes urine in a fair sized stream, but it takes him some time to get started. Nocturia, two or three times. Rectal examination reveals no mass or induration in the region of the prostate. Residual not measured.

Letter, Jan. 19, 1911, from his physician: "His health is certainly as good as it was before he was troubled with his prostate. He has at times some difficulty in passing his urine, but has no retention. Outside of some frequency, his bladder condition is good."

CASE 7. J. D., No. 154867. W. S. Age, seventy-one years. Widower. Farmer. Entered hospital Sept. 17, 1907. Service of Dr. Balch.

*History.* — Gonorrhea in youth, also one year ago. Frequency of micturition for four years. Urinates from every half to two hours by day, every half hour by night. Difficult to start stream, sometimes dribbles.

*Examination.* — Obese. By rectum prostate symmetrically enlarged, not tender. Catheter introduced with difficulty. Residual, ½ oz.

*Urine* pale, turbid, with shreds, albumen slight trace. Sediment — epithelium and mucus, gonococci found.

*Cystoscopy.* — No note.

*Operation*, Sept. 21, partial suprapubic prostatectomy. Prostate small and hard, no third lobe, but a fibrous bar behind internal meatus. Unable to shell out prostate with fingers. Bar cut through with actual cautery. Small portion of prostate removed with scissors for examination. Suprapubic drainage. Some bleeding.

*Pathological report.* — Malignant adenoma.

*Convalescence* uneventful. Oct. 19, suprapubic wound closed, micturition easy. Discharged twenty-eighth day to Convalescent Home.

*Subsequent history.* — Nov. 1, 1908, returned for examination. General condition good since leaving hospital. Frequency two or three times at night. No sign of recurrence. Catheter shows very little residual. Nov. 17, 1908, Out-Patient Department note: Frequency and pain at night, stream small, urine cloudy, residual 4 oz. May 24, 1909, prostate enlarged and hard as a rock by rectum. Residual urine, 11 oz. Taught to use a Coudé catheter.

Dec. 6, 1910, general condition good, using catheter. Bladder irrigation, no pain. Gaining weight.

PERINEAL PROSTATECTOMY FOR MALIGNANT DISEASE.

CASE 13. A. C., No. 160096. E. S. Age, sixty-two years. Married. Fisherman. Entered hospital Sept. 4, 1908. Service of Dr. Brooks.

*History.* — Denies venereal. Difficulty in passing urine for last six months. For last two weeks has had

complete retention requiring catheterization. Has lost much weight in last four weeks.

*Examination.* — Small, wiry, old man. By rectum prostate small, hard and nodular, considered probably malignant.

*Urine.* — Amount varied from 40–160 oz. daily. Specific gravity 1009, albumen trace. Slight amount of pus.

*Cystoscopy* unsatisfactory.

*Operation*, Sept. 10, 1908, partial perineal prostatectomy. Gland dense and fibrous removed piecemeal. Anterior lobe removed.

*Pathological report.* — Malignant adenoma.

*Convalescence.* — Perineal fistula persistent. Healed to a pinpoint but urine leaked through it constantly without control. Kept on urethral drainage for weeks, but fistula could not be made to close.

Nov. 9, attempt made under ether to repair fistula; it was dissected out to neck of bladder and closed with sutures, urethral drainage. When catheter was removed, urine passed through penile urethra, but without control. Perineal sinus soon broke out again. Discharged Dec. 12, 1908, ninety-second day, with incontinence and persistent perineal sinus.

*Subsequent history.* — Patient seen a few months later had recovered partial control, but perineal sinus still persisted.

Town clerk reports that patient died Sept. 11, 1909, of genito-urinary cancer.

Case 18. J. H. K., No. 163166. W. S. Age, sixty-eight years. Widower. Farmer. Entered hospital March 31, 1909. Service of Dr. Mixter.

*History.* — Gonorrhea forty years ago. No urinary trouble until two days ago, when he suddenly had retention of urine. Local physician unable to pass catheter.

*Examination.* — Large, powerfully built man. Inguinal hernia. Under ether an English catheter was passed and tied in. This did not drain properly and he was later tapped above the pubes. Perineal section for drainage of the bladder was later done.

*Cystoscopy.* — Through perineal wound, prostate, intravesically enlarged, appeared irregular in outline. Felt nodular by rectum. Considered malignant.

*Operation*, April 29, partial perineal prostatectomy. Lateral lobes dug out with difficulty.

*Pathological report.* — Cancer.

*Convalescence.* — Usual post-operative treatment. May 4, passed some urine by urethra, has control. Edema of feet, râles in lungs. May 25, discharged, twenty-sixth day. Walking about, gaining strength. More than half urine comes through urethra, good control.

*Subsequent history.* — Letter, June 2, 1910, from sister of patient states that patient died May 27, 1910. "Gained a little after leaving hospital, began to fail in October, suffered during winter and was confined to his bed from Easter until death in May."

Case 25. M. K., No. 166026. E. S. Age, eighty-one years. Married. Farmer. Entered hospital Sept. 22, 1909. Service of Dr. Brooks.

*History.* — Gonorrhea twenty-five years ago. For one year has had frequency with small amount passed at a time, ten or twelve times by day, three or four at night. No bleeding. For last two weeks frequency and pain have been increasing. Yesterday had retention requiring catheterization.

*Examination.* — Well-nourished old man. Arteriosclerosis. Bladder distended. Soft catheter easily passed and 20 oz. clear urine withdrawn. By rectum prostate hard and smooth. Considered malignant.

*Operation*, Sept. 27, 1909, perineal prostatectomy. Tissue very adherent. Usual drainage.

*Pathological report.* — Cancer.

*Convalescence.* — Control on Oct. 4. Patient up and about, and feels well. Discharged Oct. 15, eighteenth day, to local doctor. Complete control, but all urine passes through perineal wound. Wound slowly closing.

*Subsequent history.* — Letter: Daughter writes that patient died July 30, 1910. Was quite comfortable for two months after leaving hospital. Very sick in February, 1910, and after that had ups and downs until the end.

Case 27 T. D., No. 166901. E. S. Age, seventy years. Married. Laborer. Entered hospital Nov. 13, 1909. Service of Dr. Harrington.

*History.* — For past six months has had frequency and burning. For four weeks had dribbled urine constantly.

*Examination.* — Fairly well-nourished old man. Marked arteriosclerosis. Bladder distended above umbilicus. Scrotum and legs edematous. Rectal examination unsatisfactory on account of pain. Reflexes normal. Soft catheter passed, 25 oz. clear urine withdrawn.

*Urine* pale, clear, acid, 1006, albumen trace, sediment — little pus. Twenty oz. withdrawn every three hours.

*Cystoscopy.* — Prostate projects moderately into bladder cavity. Contour irregular. Suggestive of malignancy, this is confirmed by rectal touch. Prostate very hard and nodular, projects markedly into rectum. Constant drainage removed, patient unable to void.

*Operation*, Nov. 29, 1909, perineal prostatectomy. Prostate adherent to rectum, rectum opened. Prostatic lobes dug out with scissors. Rent in rectal wall closed with two layers chromicized catgut sutures. Seepage.

*Pathological report.* — Cancer.

*Convalescence.* — Packing removed on second day. Put on constant urethral drainage. Dec. 5, fecal matter in dressings. Urine and feces discharge through wound. Kept on constant drainage. Patient irrational.

Dec. 29, spinal anesthesia, suprapubic cystotomy for drainage. Rectal fistula repaired and closed with sutures. Unsuccessful.

Jan. 17, spinal anesthesia, second attempt to close rectal fistula. Sphincter cut through, edges freshened and sutured. Patient collapsed after operation. Fistula reopened in three days. Wound packed widely open. Urine and feces discharged through this opening with very little control.

Feb. 13, discharged, seventy-fourth day, to Chronic Home.

*Subsequent history.* — Patient made great improvement in general health and strength and left the Home in a month. Wound had contracted down very considerably. He had control of bowels. Letter of Dec. 14, 1910, states that patient is up and about and able to do little chores. All urine comes through the wound, passes it about every hour, has complete control day and night. His bowels are not very regular, otherwise do not trouble him. Has a good deal of pain in leg and chest. Back is bent over very much.

Case 33. J. O. B., No. 169013. W. S. Age, fifty-six years. Married. Brick yard. Entered hospital March 25, 1910. Service of Dr. Mixter.

*History.* — Cataract operation for both eyes. For two years has had increasing frequency and burning, every half hour by day, ten or fifteen times at night. Two weeks ago unable to void and since then has been catheterized by his physician.

*Examination.* — Poorly nourished, prematurely senile man. Speech slurring. Atrophy of left side of tongue. Chest examination not remarkable. Bladder distended to umbilicus. Knee-jerks absent. By rectum prostate

enlarged, hard and nodular. Temperature elevated. Put on constant drainage. Patient unable to void.

*Urine* pale, alkaline, 1004, albumen slight trace.

*Cystoscopy.* — Markedly trabeculated bladder with posterior trigonal pouch. Moderate intravesical enlargement of prostate. Two lateral lobes and two small median lobules.

Neurological consultation. Reflexes normal, not tabes.

*Operation*, April 6, spinal anesthesia, perineal prostatectomy. Usual technic. Prostate very adherent.

*Pathological report.* — Cancer.

*Convalescence* uneventful. April 16, patient voided through penile urethra for first time. General condition not improving. Wound slowly closing. Discharged April 23, seventeenth day, to local doctor.

*Subsequent history.* — Letter Jan. 11, 1911, from patient's physician: "As far as the operation for the prostate was concerned, result was good. He suffers at present no inconvenience with his bladder and passes his urine with ease. The wound is closed and there is no leakage whatever; the control of bladder is good."

CASE 36. R. M., No. 170370. E. S. Age, seventy-three years. Married. Leather dresser. Entered hospital June 15, 1910. Service of Dr. Brooks.

*History.* — Gonorrhea at sixteen. Has lost one half his weight in last five months. Last winter gave up work on account of frequent micturition. Urinates every ten minutes. Three weeks ago retention of urine. Catheterization causes bleeding.

*Examination.* — Emaciated, cachectic, old man. Dry skin, tongue dirty brownish coat, marked arteriosclerosis. Constant dribbling of urine. Prostate hard and nodular, characteristic of cancer. Residual, 20 oz. Put on constant drainage.

*Urine* bloody.

*Operation*, June 21, perineal prostatectomy. Tissue dense and adherent, removed with scissors, median bridge removed. Two small stones removed from bladder with forceps. Double tube and gauze pack.

*Pathological report.* — Adenocarcinoma.

*Convalescence.* — Uneventful. July 8, has gained some control; for first time urine passes through wound. July 27, urine still comes through wound, but with complete control. Sound No. 29 passed to bladder with ease. Residual, 2 oz. Wound slowly closing in. Patient anxious to go home. Discharged thirty-sixth day.

*Subsequent history.* — Died one month after reaching home, of pneumonia. Urinary symptoms relieved.

PERINEAL PROSTATECTOMY FOR TUBERCULOSIS.

CASE 26. J. M., No. 166711. E. S. Age, sixty years. Married. Farmer. Entered hospital Nov. 1, 1909. Service of Dr. Harrington.

*History.* — Denies venereal. Well up to three years ago, when he began to have frequent and painful urination with occasional blood. Has been treated in Out-Patient Department for one year. Many cystoscopic examinations. Patient comes in with retention. Put on constant drainage.

*Examination.* — Poorly nourished, cachectic. By rectum prostate irregular and stony hard. Considered malignant.

*Urine* acid, 1014, albumen trace, sediment — blood and pus.

*Operation*, Nov. 5, perineal prostatectomy. Two lobes removed without much difficulty, finger introduced into bladder, which is small. No median lobe. Double tube drainage and gauze pack.

*Pathological report.* — Tuberculosis.

*Convalescence.* — Tubes and packing out early. No bleeding. Temperature elevated every evening. Nov. 16, put on constant drainage to facilitate closure of sinus. Sinus very slow to close. No control of urine when catheter is removed. Put on perineal drainage. Discharged Jan. 8, 1910, with perineal drainage and rubber bottle.

*Subsequent history.* — Letter states patient died March 6, 1910.

## Clinical Department.

### FIVE SUCCESSIVE CÆSAREAN SECTIONS ON THE SAME WOMAN, THE FIFTH ON TWINS. A UNIQUE OBSTETRIC HISTORY.

BY CHARLES M. GREEN, M.D., BOSTON.

(From the Clinic of the Boston Lying-In Hospital.)

I.

S. H., negress, sixteen years of age, four feet seven inches in height, entered the Boston Lying-In Hospital Feb. 4, 1898, having been in primiparous labor twenty-two hours. The os uteri was fully dilated, the membranes unruptured, the unengaged head presented O. L. A., and the fœtal heart rate was 138. Pelvimetry disclosed a generally contracted, flat, rachitic pelvis, with a true conjugate at the brim of 6.5 cm. The case was seen by the late Dr. George Haven, who in the face of an absolute indication performed Cæsarean section, In accordance with the fixed policy of the hospital the woman was not sterilized. The uterine incision was closed with two layers of silk sutures, and the abdomen with mass sutures of silkworm gut.

The woman ran an irregular temperature of 100°–102°, and on Feb. 27 the abdominal wound broke down. There were no vomiting, distention, or other peritoneal symptoms. The wound was opened and drained, and gradually closed by granulation. On April 3, a small breast abscess was opened. After protracted convalescence the mother was discharged well on May 3; the baby, which weighed 5 lbs. at birth, was also discharged well, weighing 8 lbs. 13 oz. The woman was advised to enter for a timely section in the event of subsequent pregnancy.

II.

On March 16, 1901, S. H. re-entered the hospital, having been in labor nine hours. The os was dilated one inch, the membranes were unruptured, the head presented, O. L. A., and the fœtal heart rate was 138. After the usual preparation of the patient, Cæsarean section was performed by Dr. Green. Incision was made in the old scar and the uterus opened through adhesions without entering the peritoneal cavity. It was not easy to differentiate the tissues in the uterine and abdominal walls; but the incision was closed with two layers of silk suture, with superficial sutures of silkworm gut.

The woman made a rapid and normal convalescence, and was discharged well April 16. The baby, weighing 7.5 lbs., was also discharged well. The mother was advised to enter the hospital before the advent of labor, should she again become pregnant.

III.

In accordance with advice, S. H. entered, apparently at full term, but not in labor, on Aug. 6, 1903, and received the usual preparation for laparotomy. For the third time the head presented, O. L. A., and the fœtal heart rate was 132. Labor pains began on Aug. 7, and section was performed by Dr. Newell, who was then on duty. The uterus was opened as before through

scar tissue and adhesions without entering the peritoneum; and the incision was closed with one layer of silk sutures, and one layer of silkworm gut.

The convalescence was uneventful, and mother and baby were discharged well on Sept. 14, the baby weighing 7 lbs. 14 oz.

IV.

On Oct. 17, 1906, S. H. entered the hospital for the fourth time, apparently at term. She was not in labor, and no vaginal examination was made. Palpation disclosed a breech presentation, S. D. A.; the fœtal heart rate was 142. After the usual preparation of the woman, section was performed by Dr. Green. The uterus was opened and closed as before, except that linen sutures were used instead of silk.

After an uneventful convalescence the mother was discharged well on Nov. 13, with her baby weighing 5 lbs. 9 oz.

V.

S. H. entered for the fifth time on Feb. 10, 1909. She was apparently at term, was not in labor, and was not examined vaginally. Palpation showed twin pregnancy, — one baby presenting the head, O. L. A., with heart rate 140, the other presenting the breech, S. D. P., with pulse of 164. After two days of preparation the woman was delivered by Cæsarean section by Dr. Green. The breech baby was delivered first, and weighed 5 lbs. 9 oz.; the baby presenting the head weighed 5 lbs. 4 oz.; and the placenta weighed 1 lb. 15 oz. The total weight of twins and placenta was, therefore, 12 lbs. 12 oz. The placenta was single, with one chorion and two amniotic sacs with complete median septum. The babies were both males. The incision was closed with two layers of linen sutures and one of silkworm gut. The woman was discharged well in three weeks, after a normal convalescence. The larger baby had gained 3 oz. over its birth-weight; but the smaller baby had not nourished as well, and was 8 oz. below its birth-weight.

It was a matter of interest at the time, that the fifth Cæsarean operation on this negress was performed on the birthday anniversary of the great President who emancipated her race in this country; and the mother announced her intention of naming her twins Abraham and Lincoln respectively.

The performance of Cæsarean section for the fifth time on the same woman is no longer a unique event, either in this country or in Europe. Indeed, since the case above reported, the writer has himself successfully performed another fifth section in the same clinic. But as far as I am aware no case has ever been reported in which six babies have been delivered by five sections on the same woman.

As was intimated in the early part of this report, it is the policy of the Boston Lying-In Hospital, in the Cæsarean operation, never to remove or impair the function of healthy organs for the purpose of preventing subsequent pregnancy. The attitude of the hospital on this subject does not seem to have met with general professional approval. Apparently an opinion is held by a majority of obstetric surgeons that it is unfair to a woman to subject her for a second time to the risk of the Cæsarean operation. It is not my purpose to discuss this subject at this time; those interested in the question are referred to papers and discussions in the Transactions of the American Gynæcological Society for 1909 [1]; but it may be noted that under the policy of non-sterilization the two women who have each submitted to five sections have left the hospital with eleven healthy infants, and they themselves in excellent health.

There is another interesting feature in the case of the negress, S. H., whose utero-abdominal incision sloughed in her first convalescence. The result of this surgical misadventure was a firm, broad, high fixation of the uterus to the anterior abdominal wall, so that in four subsequent sections the peritoneal cavity was not entered, and convalescence progressed without untoward incident. Moreover, the abnormal position of the uterus, with the fundus reaching nearly to the umbilicus, produced no unpleasant symptoms. It therefore seemed to me legitimate to try the effect of producing a sufficiently long and broad artificial utero-abdominal fixation with a view to subsequent extraperitoneal section. I have, therefore, done this operation in two cases of young primiparæ, each with an absolute indication, after performing their first Cæsarean section. Both of these women were discharged in good condition with their infants, and I await a second section with interest. If my technique proves successful, these two women should be delivered by extraperitoneal incision repeated any number of times with a negligible risk.

## A SUMMER SERVICE IN THE WELD WARD OF THE MASSACHUSETTS GENERAL HOSPITAL.

BY CHARLES J. WHITE, M.D.,
*Instructor in Dermatology in Harvard University.*

This ward of twenty beds, built by private generosity, was opened in October, 1903, and has proved of great benefit to many patients who otherwise would have found great difficulty in caring for their peculiar, and often crippling, diseases. Secondly, this ward has been of great service to the community in isolating many highly contagious cases of syphilis until their open wounds have cicatrized and thus rendered them less dangerous to their neighbors. Thirdly, this ward has been of great value to its staff and to medical students, who have found within its beds practically all the common diseases in their severest forms, and most of the rarest dermatoses. These beds have been the means of keeping within the hospital these many patients whose diseases could, therefore, be observed and studied until convalescence or death completed the cycle of their disease.

The service last summer, extending from July 1 to Oct. 1, was a typical one in most respects and was marked by the appearance of many interesting dermatoses, so that it seems worth while, since in our case this has never been done before, to publish the record of the more common diseases and to describe in a few words the rarer ones.

[1] The writer's paper may also be found in the American Journal of Obstetrics, vol. lix, no. 6, 1909.

CASE 1. *Syphilis.* Man aged twenty-three, laborer. Two years ago chancre developed on prepuce. To-day both legs and thighs show numerous large ulcers, some of which have coalesced to form denuded areas covering large portions of the limb. Over the rest of the body are many scars, some keloidal, some pigmented, which vary in size from that of a ten-cent piece to larger areas occupying nearly the whole forearm and elbows. From the active lesions a foul-smelling pus was exuded.

Apart from the extensive destruction present in this patient his case is interesting because of the long time necessary to reproduce a whole and sound integument. Despite the use of the most varied hygienic, antisyphilitic, dermatological and surgical remedies, the man was in the ward off and on for nine months. This would have been a splendid case for "606," but unfortunately none was obtainable.

CASE 2. *Syphilis.* Woman aged twenty-three, housework.

A case somewhat similar to the last. Several ulcers were present, the largest of which dated back three years and was on the lower leg, measuring 5½ by 4½ by 3½ inches. The woman was also pregnant and at the time of her discharge three and one-half months after entrance fetal movements were noticeable and the patient had gained 23 lbs. Nevertheless, mother and child died later at a state hospital.

CASE 3. *Psoriasis.* Woman aged forty-seven, housewife.

Eruption generalized over scalp, face and body. Disease began thirteen years ago, disappeared six years later during an attack of toxemia and reappeared six months afterward while under the influence of the grippe. The patient showed a marked idiosyncrasy toward salicylic acid, developing delirium and great weakness after the application over the whole surface of an ointment containing this drug.

CASE 4. *Granuloma Annulare.* Female aged eight. Father has tuberculosis, only case in family. Scarlet fever two years ago, whooping cough last winter. Physical examination negative except for cutaneous eruption, which first appeared six weeks ago. To-day there is on the flexor surface of the left index finger, a painless oval ring 1½ inches in diameter. The ring is elevated ¼ inch above the surface, is white, firm and elastic, and somewhat nodular. The center is probably at the level of the normal skin, and is free from abnormal signs except for a somewhat purplish color. Over the middle joint of the right index finger on the extensor surface is a circular line of papules, rather ill-defined, red in color, ¾ inch in diameter, the arrangement producing a ring-shaped eruption resembling its fellow on the left finger. The rings continued to extend peripherally, the larger one gaining ¼ inch in diameter, and some of the individual papules became delled and glistening. This advance continued for about six weeks and then x-ray exposures were begun, and at the end of a week distinct softening of the lesions had begun, although the periphery had continued to extend. Three weeks after the institution of the rays the lesions were level with the normal skin, but the extent of the previous process could be seen clearly by the color differences of the healthy and the abnormal skin.

HISTOLOGY. (BIOPSY.)

*Epidermis.* — The stratum germinativum is normal, but the overlying rete cells change abruptly. The protoplasm of the cell shrinks, leaving the nucleus occupying the larger portion of the cell structure; or the protoplasm around the nucleus disappears, leaving conspicuous perinuclear halos; or again, the nuclear protoplasm rarefies, leaving a clear space containing chromatin granules floating within the nuclear rim. The stratum granulosum is hyperplastic and dense. The cell boundaries are very indistinct and the layer as a whole seems compressed. Above this layer is an indeterminate zone, basic in its affinity and difficult to name. It is very compact and contains many elongated flattened nuclei without granules. This zone occupies the area of the stratum lucidum, but can hardly be designated by this name. Above this debatable ground appears a very hyperplastic stratum corneum which is almost twice as thick as the whole underlying epidermis. It is wholly atypical and consists of swollen horny cells full of vesicular spaces, most of which seem to hold a degenerated nucleus containing granular matter.

*Corium.* — The subpapillary layer is rather rarefied and holds numerous vessels, many of which are slightly dilated and surrounded by lymphocytes. On the other hand, some of these vessels show endothelial thickening. Below this level the corium becomes highly pathological and contains many lobules contiguous to one another and separated by more or less vertical or slanting bands of fibrous tissue. The lobules themselves are composed of short, dense connective tissue cells containing many lymphocytes. Within these lobules are large veins exhibiting considerable endothelial and perithelial thickening, and here and there total obliteration. Sweat glands, when present, seem compressed, and their lumen is much restricted in diameter. These structures seem to be analogous to the cellular invasions of the fat cells observed in erythema induratum, and in places in these sections this invasion and final obliteration of the panniculus adiposus can be well observed. No giant cells, however, can be noted.
